Executive Summary

With the expectation that the trophic status of Lake Taupo will slowly change to reflect changes in land use within the lake's catchments, a long term programme monitoring the lake's water quality was commissioned by Environment Waikato. This programme commenced in October 1994 and is conducted by NIWA with field assistance from the Department of Internal Affairs, Taupo Harbourmaster's Office.

The monitoring programme was designed to detect change through assessment of the rate of consumption of oxygen from the bottom waters of the lake (volumetric hypolimnetic oxygen depletion – VHOD) as an integration of all biological processes occurring in Lake Taupo. Additional parameters are measured to provide a more comprehensive picture of water quality. Recently it has become apparent that VHOD may be too coarse to determine trophic change in a lake the size and complexity of Lake Taupo. Consequently, more emphasis is now focused on the parameters 'phytoplankton biomass', 'water clarity', and nutrient (particularly nitrate) accumulation in the lake. This report presents the results from the 2004/05 monitoring period at the mid-lake site, Site A. Monitoring of additional sites in the Kuratau Basin (Site B) and the Western Bays (Site C) between January 2002 and December 2004 determined that spatial variability of water quality across Lake Taupo is minimal and that it is valid to use the mid-lake site as representative of the open water quality of the lake.

While there is still a long-term trend of increasing phytoplankton biomass (chlorophyll *a*) over the monitoring period of $0.054 \pm 0.036 \text{ mg m}^{-3} \text{ y}^{-1}$ the 2005 year was unusual in that chlorophyll *a* concentrations were lower than in the previous five years in both winter and summer. The lower winter peak in chlorophyll *a* may be attributed to the incomplete mixing of the lake in winter 2005 and a retention of about 50% of the accumulated mass of $\text{NO}_3\text{-N}$ in the bottom waters that would normally have been mixed up into the surface waters.

Highest biomass occurred in August when the lake had mixed and lowest biomass occurred in early summer when that winter biomass peak had sedimented from the water column. The 2004 winter bloom was dominated by the diatom *Fragilaria crotonensis* but included *Asterionella formosa*. In winter 2004 the dominant species were *Asterionella formosa* and *Aulacoseira granulata*. In summer, *Oocystis* sp. and *Botryococcus braunii* were co-dominant and were replaced with *Cyclotella stelligera* and *Ceratium hirundinella* through late summer and autumn.

Blue-green algae (*Anabaena flos-aquae* and *Aphanizomenon* sp.) were present throughout the lake in increasing abundance from about November 2004 but rarely exceeded 3rd level order of dominance at the mid lake site. *Anabaena flos-aquae* became the dominant species briefly in May 2005 but had disappeared by June.

Nutrient concentrations (DRP, NH₄-N, and NO₃-N) in the upper water column were comparable with concentrations since 2003. DRP and NO₃-N concentrations rose during initial winter mixing and then were depleted as phytoplankton grew although DRP was much slower to be depleted than NO₃-N. The peak concentration of DRP at winter mixing 2005 was the highest ever recorded at 3.9 mg m⁻³. The summer concentrations of NH₄-N and NO₃-N were below detection level on most occasions. Bottom water (150 m) NO₃-N and DRP concentrations increased at similar rates to the previous year. The accumulated mass of NO₃-N and DRP in the hypolimnion before winter mixing has been similar for each of the last three years but is presently about twice the accumulated mass recorded in the hypolimnion at the beginning of the present monitoring programme in 1994/95. From historic data, the accumulated mass of NO₃-N in the hypolimnion by autumn each year since 1975 is increasing at a statistically significant rate of about 11 t y⁻¹ ($P < 0.001$, $r^2 = 0.59$, $n = 17$).

During the 2004/05 monitoring period, summer water clarity was high for an extended period reaching a Secchi disc depth of 20.7 m in February 2005 and remaining above 19 m from January to late March 2005. Water clarity in winter 2005 was higher than previously recorded, remaining above 13 m. This can also be attributed to incomplete mixing and the concomitant low winter algal biomass. Since January 2003, there has been a strong inverse relationship between chlorophyll *a* and water clarity ($P << 0.0001$, $r^2 = 0.55$, $n = 47$).

The 2004/05 net VHOD rate at 11.30 ± 1.13 mg m⁻³ d⁻¹ (mean \pm 95% confidence limit) was about same as the previous year, 11.50 ± 2.80 mg m⁻³ d⁻¹. The present VHOD rates are more than 2 mg m⁻³ d⁻¹ higher than in 1994/95 and 1995/96.

In the 2002 review of the long-term monitoring programme data, 3 trends in the data were identified — increasing phytoplankton biomass in the upper 10 m, increasing NO₃-N mass in the hypolimnion prior to winter mixing, and an increasing range in the variability of water clarity — that were of concern with respect to the water quality of Lake Taupo. These trends are still present in the data.

Glossary

BOD	Biochemical Oxygen Demand: the rate of oxygen consumption associated with biological decomposition and chemical processes and in the water column.
VHOD	Volumetric Hypolimnetic Oxygen Demand: the net rate of oxygen loss associated with biological, chemical and physical processes in the hypolimnion of a lake in the absence of a temperature change
Phytoplankton	Microscopic free-floating aquatic plants (algae)
Cyanobacteria	Blue-green algae. These are potentially toxic. They can adjust their depth in the water column using small gas bladders (gas vacuoles), and some species can use (i.e., fix) atmospheric nitrogen for growth when nutrient nitrogen in the water column is depleted.
Zooplankton	Small to microscopic free-swimming aquatic animals which graze on phytoplankton or smaller zooplankton
Biomass	The living mass of the phytoplankton or zooplankton populations
Thermal stratification	Separation of a water column into two layers by temperature – warmer water on top
Thermocline	The boundary zone or temperature gradient between the two layers in a thermally stratified water column.
Epilimnion	The upper water column in a thermally stratified water column
Hypolimnion	The lower water column in a thermally stratified water column
Metalimnion	The thermocline zone — of variable thickness
Euphotic zone	The upper water column in which there is sufficient light for photosynthesis and hence phytoplankton growth
Nutrients	Essential dissolved inorganic nitrogen and phosphorus compounds which can be used directly by plants for growth
Ammoniacal nitrogen	Sum of ammonium ion (NH_4^+) plus free (unionised) ammonia (NH_3). Some amines (NH_2^-) may be included as interference during analysis. Symbol, $\text{NH}_4\text{-N}$.
Nitrate nitrogen	Used in this report as the sum of nitrate (NO_3^-) plus nitrite (NO_2^-). Symbol, $\text{NO}_3\text{-N}$.
DIN	Dissolved Inorganic Nitrogen: the sum of $\text{NH}_4\text{-N} + \text{NO}_3\text{-N}$
DON	Dissolved Organic Nitrogen: the soluble nitrogen other than DIN
PN	Particulate Nitrogen: includes phytoplankton and other detritus
TN	Total Nitrogen: Sum of DIN + DON + PN
NO _x	Gaseous oxides of nitrogen, including N_2O , NO, NO_2

1. Introduction

With the expectation that the trophic status of Lake Taupo will slowly change to reflect changes in land use within the lake's catchments, a long term monitoring programme of the lake's water quality was commissioned by Environment Waikato. This programme commenced in October 1994 and is conducted by NIWA with field assistance from the Department of Internal Affairs, Taupo Harbourmaster's Office. The monitoring precision was augmented from February 1999 by the use of a new profiling instrument – a Richard Brancker Research model RBR410 conductivity-temperature-depth (CTD) profiler/logger fitted with a Yellow Springs Instrument (YSI) model 5739 dissolved oxygen (DO) probe. In January 2002, this instrument was upgraded to a Richard Brancker Research model XR420f freshwater profiler/logger with improved sensitivity. The new profiler is fitted with a YSI model 5739 DO probe as well as a Sea Point Chlorophyll Fluorometer to give *in situ* estimates of vertical distribution of algal biomass within the lake water column. This report presents data from the routine mid-lake monitoring station from August 2004 to September 2005.

The 2000 – 2001 annual report (Gibbs et al. 2002) reviewed the monitoring data accumulated since 1994, relating it to the known sensitivity of Lake Taupo to nitrogen (N), and known increased N loading from the catchment. A continuation of that assessment in such detail is not included in this report. Rather, the new data are presented in the context of the long-term data set, and a further review will be provided in a future report.

In the two previous reports, data was included from two additional sites representing those historically measured in the 1974-76 assessment of lake water quality (White et al. 1980) (Fig.1) to evaluate spatial variability of water quality across the lake. Results from these additional sites showed that, in general, there was minimal variation between the sites spatially or with season and that data collected from site A (mid lake) could be used as being representative of the main body of the lake. This report presents data from site A only.

The monitoring programme has 3 components: bottom water oxygen depletion, upper water column water quality, and whole water column water quality. Bottom water oxygen depletion is estimated as the volumetric hypolimnetic oxygen depletion (VHOD) rate, which is sensitive to changes in trophic status of lakes that thermally stratify for part of the year (Burns 1995). VHOD was chosen as the parameter most likely to detect a change in the water quality of Lake Taupo. Estimates of VHOD are made from dissolved oxygen and temperature profiles measured at 2-3 week intervals

during the stratified period. However, the VHOD rate will only indicate that a change has occurred and will not detect other indicators of changing water quality. For that purpose, the upper water column is sampled for nutrients, chlorophyll *a*, phytoplankton species composition and water clarity at 2-3 weekly intervals, and the whole lake water quality is estimated from a full profiles which are made twice during the stratified period. The first profile is in spring, when thermal stratification has become established and is stable. The second is in autumn the following year before thermal stratification begins to break down, and the thermocline deepens.

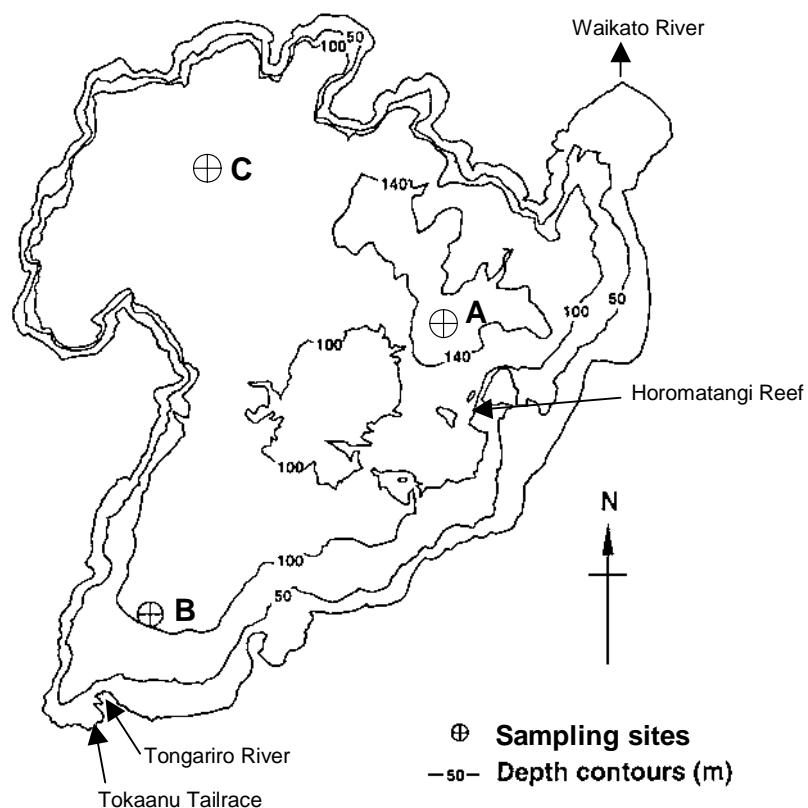

Figure 1: Site map of Lake Taupo showing location of the routine monitoring site at mid-lake (A), and the two additional sites at Kuratau Basin (B) and the Western Bays (C) sampled in the previous two years. The generally close agreement between most data from the three sites gives confidence in the past and future use of the site A data as representing the water quality of the whole lake.

2. Methods

Detailed method descriptions are given in Appendix 1. The parameters measured routinely at 2-3 weekly intervals are:

- depth-related temperature and dissolved oxygen (DO), using the RBR XR420f CTD profiler. Additional parameters of conductivity and chlorophyll fluorescence recorded by the profiler sensors are available at NIWA and will only be reported as appropriate;
- water clarity by Secchi disc depth;
- chlorophyll *a*, nitrate+nitrite N (NO₃-N), ammoniacal-N (NH₄-N), dissolved organic N (DON), particulate N (PN), total nitrogen (TN), dissolved reactive phosphorus (DRP), dissolved organic phosphorus (DOP), particulate phosphorus (PP), total phosphorus (TP), and algal species dominance in integrated-tube water samples from the top 10 m.

Water samples have also been collected at the same time from just above the lake bed (150 m) for analysis of NO₃-N, NH₄-N, and DRP to assess nutrient accumulation in the hypolimnion and to assess the extent of winter mixing.

For whole water column sampling, the parameters measured at 10 m depth intervals from the surface to the bottom of the lake twice a year are:

- conductivity, pH, temperature, DO, chlorophyll *a*, DRP, DOP, PP, TP, NO₃-N, NH₄-N, DON, PN, TN, urea nitrogen (Urea-N), total suspended solids (SS), volatile suspended solids (VSS), particulate carbon (PC), and dissolved organic carbon (DOC).

Additional parameters measured twice yearly, but not as complete profiles were:

- algal species composition and abundance on water samples from 1, 10, 50, 100 and 140 m.

Details of data handling and the treatment of values about analytical detection limits in this report are described in Appendix 1.

2.1 Report contents

This report presents the results from the 2004/2005 stratified period plus the winter mixing, and refers to data in previous annual monitoring reports from 1995 to 2005 (Gibbs 1995, 1997a, 1997b, 1998, 2000a, 2000b, 2002, 2004, 2005; Gibbs et al. 2002) for inter-annual comparisons, and archived historical data since 1974 held by NIWA. The methods used are as per the 1994/95 report and a copy of these methods is included in Appendix 1. The calculation of the net VHOD rate, as applied to Lake Taupo data, was described in the 1996/97 report and a copy is presented in Appendix 2. Copies of temperature and dissolved oxygen, and nutrient data from the previous eight years are included in Appendix 3 and 4 respectively. Graphical presentations of historical time-series temperature, dissolved oxygen, and Secchi disc depth data collected since the start of this monitoring programme are updated and presented in figures in the text. Phytoplankton species composition and dominance data for 2004/05 are included in Appendix 5 and discussed in the text. Graphical presentations of all available chlorophyll *a* concentration and Secchi depth water clarity data are presented where appropriate.

2.2 Statistical evaluation

Simple statistical evaluation of data has been made using Microsoft Excel[®] and regression results have been reported to \pm 95% confidence limits. Statistical significance (P), where used, is qualified with the coefficient of determination (r^2) and the number of data points used (n). For details see Statistical Methods, Appendix 1.

Note that statistical significance is dependent on the number of data points used. Comparisons between trends should only be made where there are similar numbers of data points.

2.3 “TREND” definition

As in previous reports, the word “trend” is used in the context of a change between the start and the end of a time series data set where the use of a linear regression analysis shows a statistically significant difference from the null hypothesis of there being no change. Use of the word “trend” is a statistical one. It does not imply any valid *extrapolation* of the observed change beyond the period of the data set being examined by the linear regression.

3. Results and discussion

3.1 Temperature and dissolved oxygen

Depth profiles of temperature and dissolved oxygen (DO) were measured at the mid lake site, Site A (Fig. 1), at about 2-3 weekly intervals, depending on the weather, throughout the year. These data, plus profiles measured during the full water quality samplings at Site A on 21 November 2004 (spring) and 21 April 2005 (autumn), are presented in Appendix 3. The time-series temperature and DO data from specific depths of 20 m (epilimnion) and 130 m (hypolimnion) collected in the monitoring programme since 1994 are presented in Figure 2.

Temperature and DO data indicate that Lake Taupo was strongly mixed in winter 2004 which produced a rapid reduction in bottom water temperature of about 1 °C, from 11.49 °C to 10.55 °C (Fig. 2A), and the lake remained thermally mixed from mid July to mid September. A likely mechanism for this stepwise change is presented in the previous report. In contrast, and of significance in this report, mixing in winter 2005 was weak and of short duration lasting less than 2 weeks in mid August. Consequently there was little cooling of the hypolimnion in winter 2005. Surface water temperatures in December 2004 and 2005 were colder than normal for that month although summer 2004/05 temperatures were generally warmer than normal.

Dissolved oxygen concentrations in the bottom waters are almost always depleted relative to surface waters and often fail to reach saturation levels during winter mixing, even when the water column temperatures are isothermal. This indicates insufficient time during the mixed period for complete re-oxygenation of the whole water column (Fig. 2B). Even the apparently strong mixing event in winter 2004, which dramatically lowered the temperature of the whole lake, failed to produce complete re-oxygenation of the whole lake although the higher oxygen concentrations in the bottom waters lasted for several weeks. In contrast, the short duration mixing in winter 2005 produced only one value approaching saturation before bottom water oxygen consumption resumed.

Of some interest is the degree of oxygen depletion observed in the 2004/05 stratification period. While in previous years the DO concentrations have fallen below 7 g m⁻³, in Autumn 2005, the minimum DO concentration recorded was 7.35 g m⁻³. This is reflected in the lower VHOD rate for the 2004/05 stratification period.

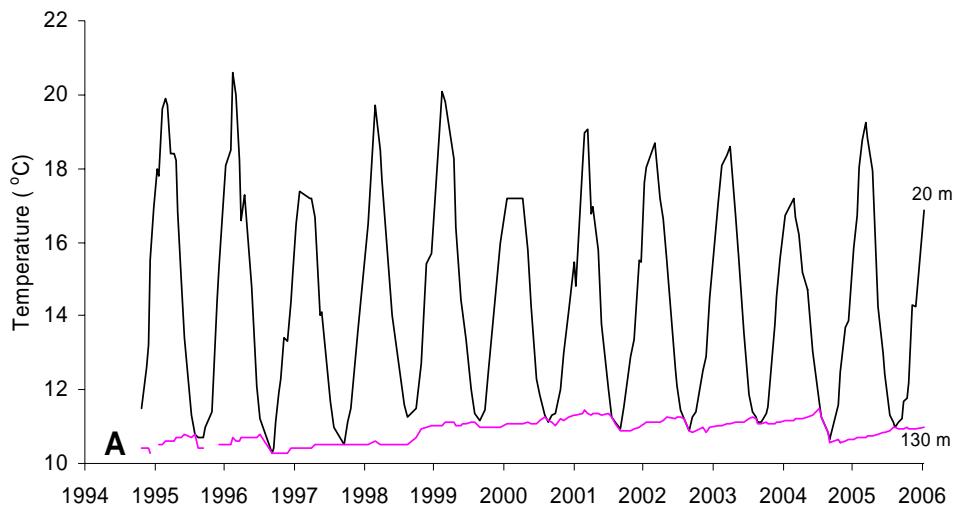

Figure 2A: Time-series temperature from 20 m (black line) and 130 m (pink line) depths. Winter mixing occurred where these two lines meet. The data show the lack of mixing in winter 1998 and only partial mixing in 1999. The strong mixing in 2004 was accompanied by a rapid cooling of the whole lake by around 1 $^{\circ}\text{C}$.

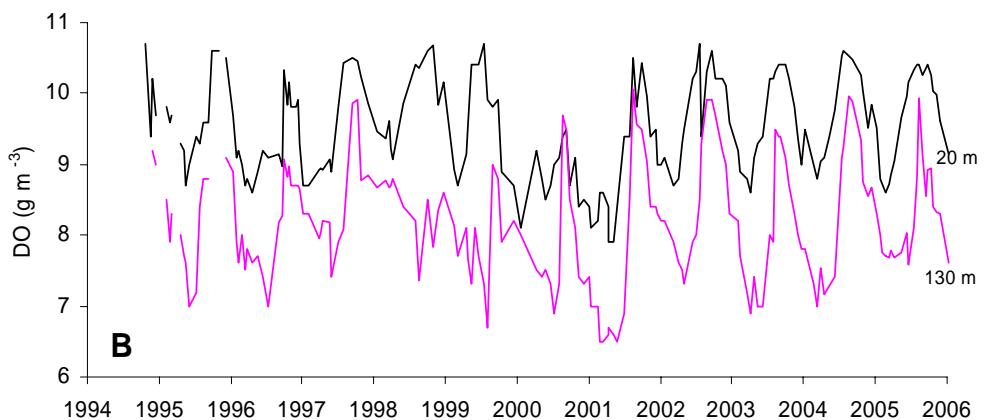

Figure 2B: Time-series dissolved oxygen data from 20 m (black line) and 130 m (pink line) depths. Mixing and complete reoxygenation occurred where the 2 lines in the temperature data (Fig. 2A) meet each winter. This corresponds with the period that the 2 lines on the oxygen data meet. However, where temperature data indicate mixing and the 2 lines of the oxygen data do not meet, there is incomplete reoxygenation (see text).

3.2 VHOD rate

The VHOD rate was estimated between October 2004 and March 2005 based on oxygen profile data collected at site A (Mid Lake). The VHOD rate in 2004/2005 was $11.30 \pm 1.13 \text{ mg m}^{-3} \text{ d}^{-1}$ (mean \pm 95% confidence limit) (Fig. 3).

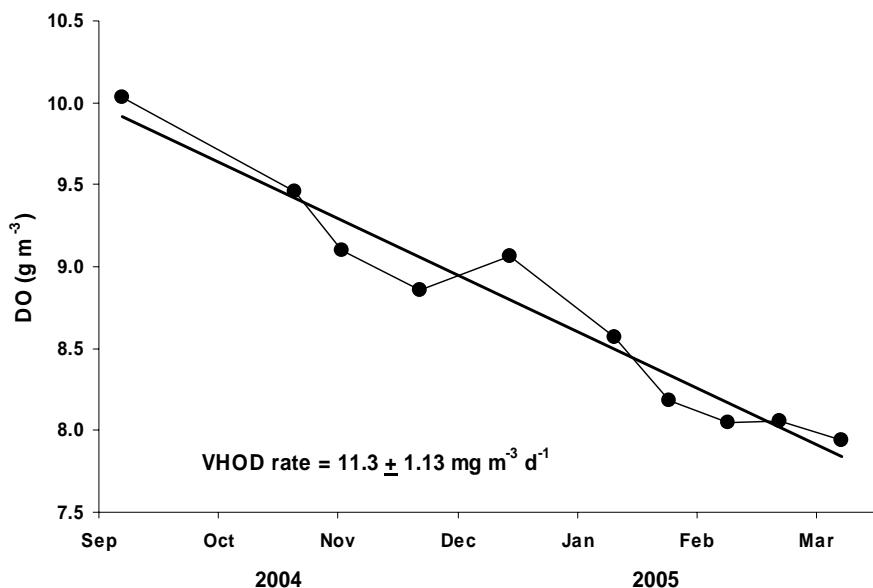

Figure 3: VHOD data and linear regression of 2004/2005. ($P << 0.001$, $r^2 = 0.9215$, $n = 10$).

Table 1: Summary of VHOD rates (\pm 95% confidence limit) and the dominant phytoplankton species during the preceding winter bloom.

Year	VHOD rate	Dominant phytoplankton species	
1994-95	8.93 (2.39)	<i>Aulacoseira granulata</i> *	Diatom
1995-96	9.07 (2.77)	<i>A. granulata</i>	Diatom
1996-97	5.12 (1.37)	<i>Botryococcus braunii</i>	Colonial green
1997-98	3.21 (2.03)	<i>B. braunii</i>	Colonial green
1998-99	2.64 (1.90)	<i>B. braunii</i>	Colonial green
1999-00	5.11 (1.14)	<i>B. braunii</i> + <i>A. granulata</i> + <i>Cyclotella stelligera</i>	C.G. – Diatom mix
2000-01	9.34 (2.9)	<i>A. granulata</i>	Diatom
2001-02	9.06 (2.7)	<i>Asterionella formosa</i>	Diatom
2002-03	13.76 (2.14)	<i>A. formosa</i> + <i>A. granulata</i>	Diatom
2003-04	11.50 (2.80)	<i>A. formosa</i> + <i>A. granulata</i>	Diatom
2004-05	11.30 (1.13)	<i>Fragilaria crotonensis</i> + <i>A. formosa</i>	Diatom

* Not measured in winter but measured in October 1994.

The 2004/2005 VHOD rate at $11.30 \pm 1.13 \text{ mg m}^{-3} \text{ d}^{-1}$ is comparable with the value for the previous year, $11.50 \pm 2.80 \text{ mg m}^{-3} \text{ d}^{-1}$ (Table 1). The last two VHOD rates are 2 $\text{mg m}^{-3} \text{ d}^{-1}$ higher than the level of $9 \text{ mg m}^{-3} \text{ d}^{-1}$ which was suggested as a possible “normal” value for the lake (Gibbs 2002).

3.3 Secchi depth

The time-series Secchi depth data (Fig. 4) show that the annual cycle of water clarity is low in winter and high in summer and mostly lies within the range of 10 – 20 m and has a mean value of 15.7 m for the period shown. The annual cyclical pattern inversely follows the seasonal pattern of phytoplankton abundance, with low clarity during the winter/spring growth phase and high clarity during summer when the phytoplankton have sedimented out of the water column. Winter 2005 had higher water clarity than winter 2004 and was the clearest full winter on record (Fig. 5). The relatively smooth cycle through 2004 and 2005 differs from some of the earlier data (Fig. 5) which show much higher variability in water clarity at different times of the year while still retaining the underlying seasonal cycle of low winter but high summer water clarity.

The reason for the often very short duration low clarity events are uncertain but may be related to storm events. These can be followed by a rapid growth in phytoplankton in response to sediment and nutrient inputs to the surface waters from land drainage. The appearance of cyanophytes in some summers since 2000 may have also contributed to that variability. The clearest water is associated with calm weather, which allows the phytoplankton and other particulate material to sediment out of the upper water column. While the expectation would be for the clear phase to occur in late December after the collapse of the winter-spring bloom, the highest clarity recorded in this data set, 22 m Secchi depth, occurred in during calm weather in autumn (April) 2002 after a summer algal bloom collapsed. During the 2004/05 stratification period, the highest clarity, 21.5 m Secchi depth, also occurred in autumn (March) (Fig. 4). Both periods of high clarity were of apparent short duration and it is possible that such clear phases may have been missed in other years due to the timing of sampling.

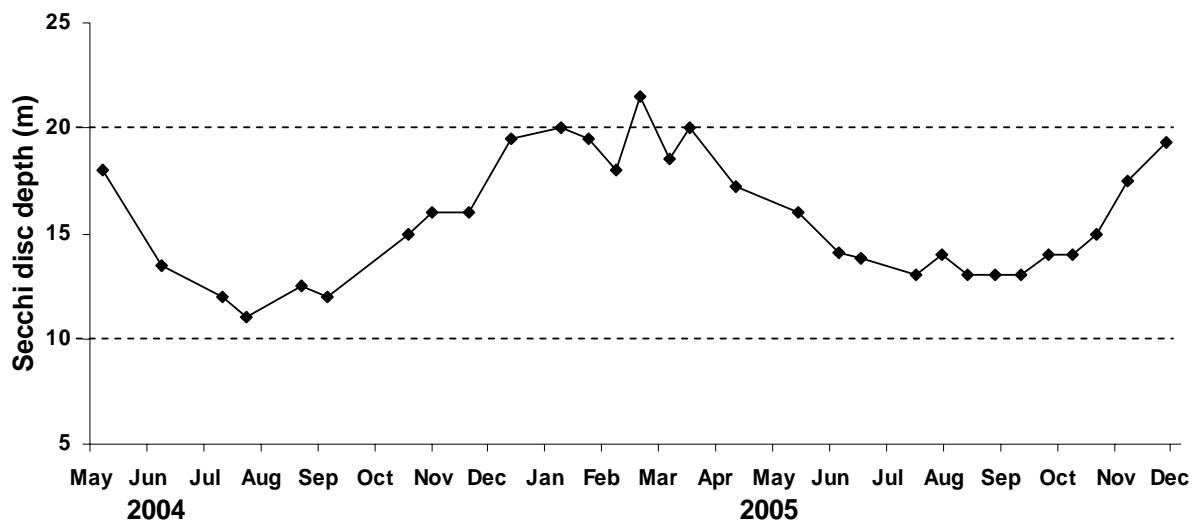

Figure 4: Water clarity as indicated by Secchi disk depth from winter 2004 through winter 2005. Broken lines represent 10 m and 20 m.

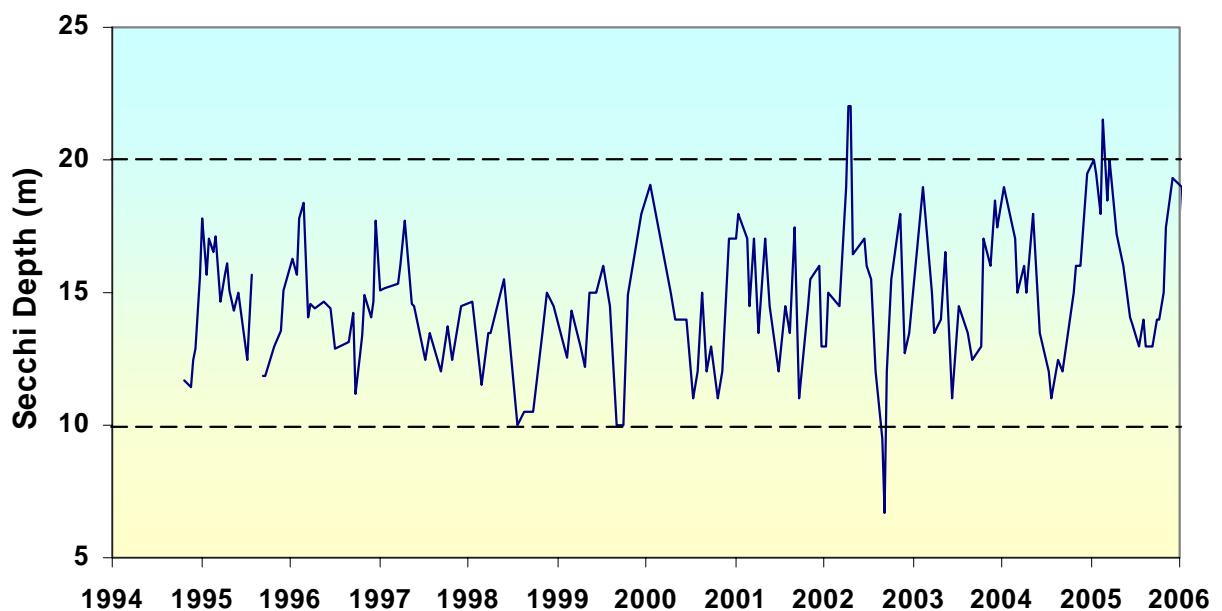

Figure 5: Long-term changes in water clarity as indicated by Secchi depth shows the variability across seasons and years for the present monitoring programme since 1994. The broken lines mark 10 m and 20 m.

3.4 Phytoplankton

While the long-term trend of increasing chlorophyll *a* concentration in the upper 10 m of the water column at the mid lake site, has continued the 2004-2005 concentrations in both winter and summer were lower than in the previous five years. This has resulted in the mean rate of increase [all data] reducing from $0.072 \pm 0.027 \text{ mg m}^{-3} \text{ y}^{-1}$ to $0.054 \pm 0.036 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P < 0.0001$, $r^2 = 0.09$, $n = 176$) (Fig. 6).

The overall pattern of chlorophyll *a* concentration changes since 1994 is one of maximum concentrations during the winter algal bloom and minimum concentrations in early summer and there is a statistically significant inverse logarithmic relationship between chlorophyll *a* concentration and Secchi disk depth ($P << 0.0001$, $r^2 = 0.21$, $n = 175$) (Fig.7A). Since January 2003, however, the seasonal cycle in the chlorophyll *a* data has become more pronounced without the additional non-seasonal peaks seen in earlier years. This change is also seen in the Secchi depth data with a stronger inverse log relationship between chlorophyll *a* concentration and Secchi disk depth ($P << 0.0001$, $r^2 = 0.69$, $n = 47$) (Fig. 7B).

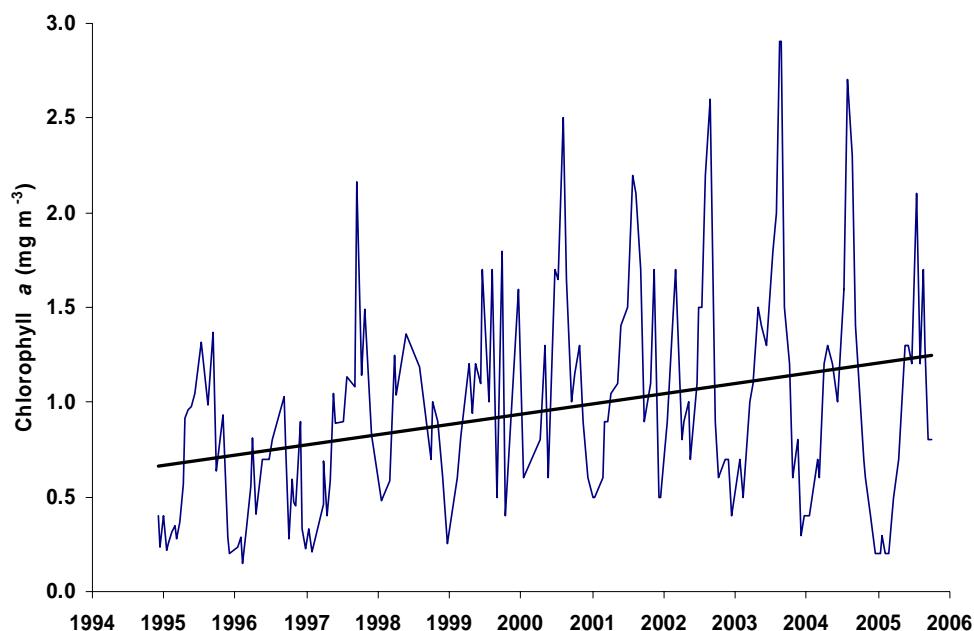

Figure 6: Time-series chlorophyll *a* concentrations in the upper 10 m of Lake Taupo at the mid-lake site, Site A. The solid regression line represents a statistically significant increase in the mean chlorophyll *a* concentrations of $0.054 \pm 0.036 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P < 0.01$, $r^2 = 0.49$, $n = 12$).

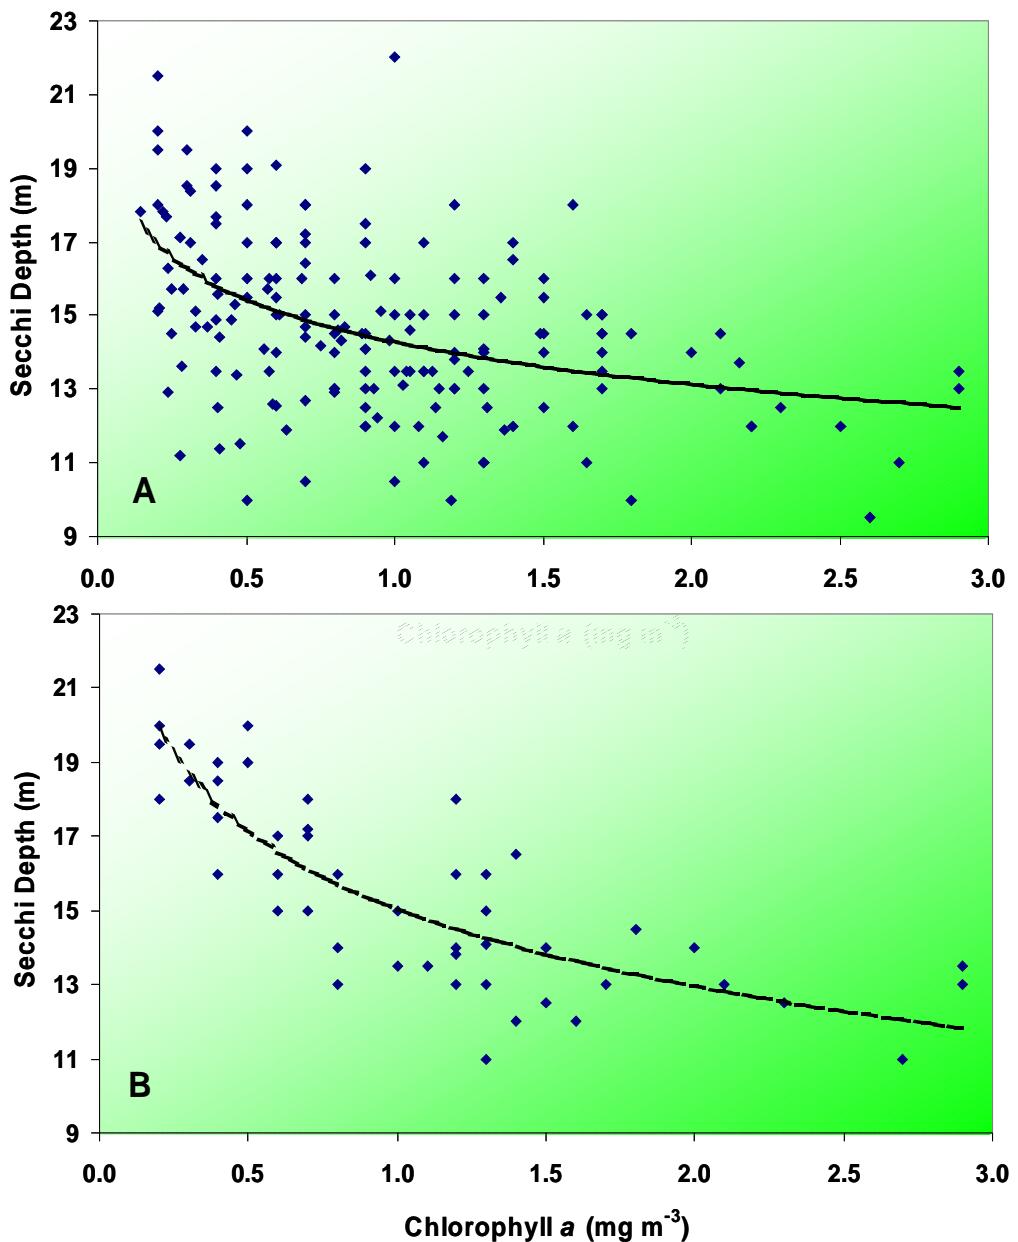

Figure 7: Inverse logarithmic relationship between Secchi disk depth and chlorophyll *a* data (A) all data since 1994 [$r^2 = 0.21$], (B) data since January 2003 [$r^2 = 0.69$].

The r^2 of 0.69 that describes the relationship between Secchi depth and chlorophyll *a* from 2003 to the present, versus an r^2 of 0.21 for the full data set, suggests that algal biomass has played a greater role in determining water clarity than in previous years.

Summer chlorophyll fluorescence profiles show a deep chlorophyll maximum just below the thermocline (e.g., 40 m). The comparison of contoured chlorophyll

fluorescence data with temperature data for the period from July 2004 to July 2005 (Fig. 8) demonstrates the changes in the depth distribution of phytoplankton in the water column of Lake Taupo over the seasonal cycle.

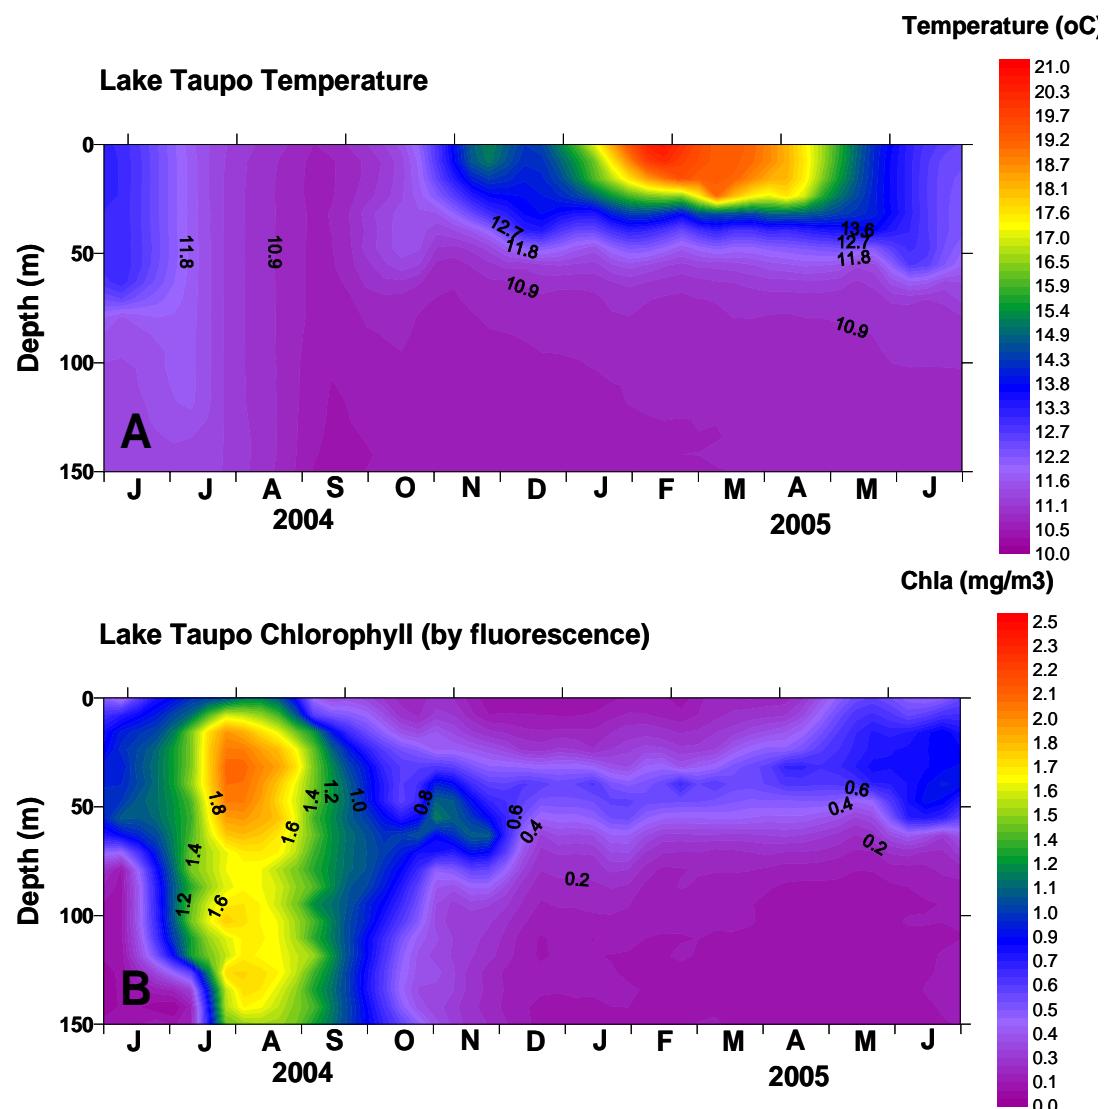

Figure 8: Time-series versus depth contour plots of (A) temperature and (B) chlorophyll fluorescence data from the RBR XR420f profiler at the mid-lake site in Lake Taupo for the period July 2004 to June 2005 showing the depth distribution of algal biomass relative to the physical (temperature) structure of the lake over the seasonal cycle.

Algal fluorescence quenching due to high summer light levels causes apparent low chlorophyll fluorescence values in the surface 10-15m between November and April and to a lesser extent at other times of the year. However, this localised phenomenon does not affect the overall depth distribution patterns shown in Fig. 8B. This plot shows that deep algal biomass in summer will not be recorded in the upper 10 m tube

data and will not affect the clarity of the lake as estimated by Secchi depth. The deep algal biomass is almost certainly being supported by the combination of nutrient diffusion up through the thermocline from the hypolimnion and light penetration down through the clear surface water at that time of year.

3.5 Species abundance

In the 2003-04 monitoring period, there were numerous algal species present in the lake (Appendix 5) with most species being present at very low levels. For the 5 major algal species which reached a dominance level of 1 to 3 (1 = dominant, 10 = rare) at Site A, the annual succession of algal species saw *Oocytsis* sp. and *Botryococcus braunii* being co-dominant in summer with *Cyclotella stelligera* and *Ceratium hirundinella* becoming co-dominant through late summer and autumn. *Fragilaria crotonensis* was the dominant species in winter 2004 but *Asterionella formosa* and *Aulacoseira granulata* were the co-dominant species during the 2005 winter–spring bloom period. Progression from a diatom dominated algal assemblage in winter to green algal dominance in summer is not unusual in Lake Taupo (Gibbs 2005).

Cyanophytes were a minor component of the algal assemblage on most occasions except April through June 2005 when *Anabaena flos-aquae* was dominant (May) or co-dominant. Measurement of low levels of cyanophytes at the mid-lake station does not necessarily reflect their apparent abundance in the inshore waters and localised wind-drift accumulation of buoyant cyanophytes can be found in embayments when the weather conditions are favourable. For example, an accumulation of the cyanophyte, *Anabaena flos-aquae* (Fig. 9), was reported in Acacia Bay in late August 2005 by local Taupo resident, Nick Bradford. This was at a time when this species was ranked around 8 in dominance at the mid-lake site.

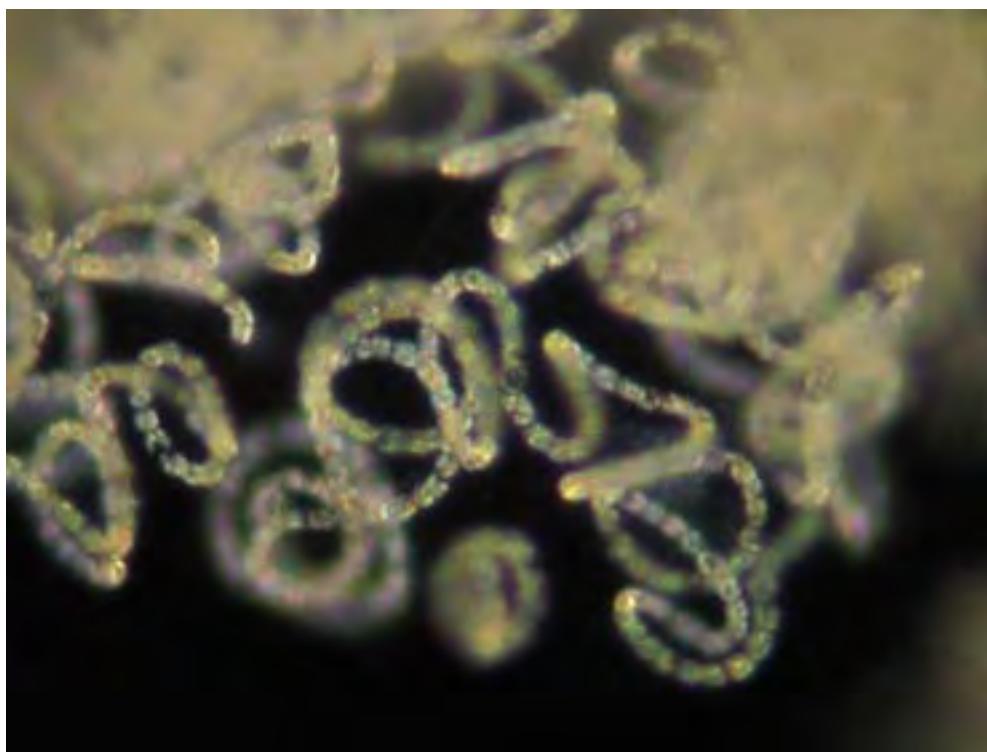

Figure 9: *Anabaena flos-aquae* from Acacia Bay late August 2005. Photo by Nick Bradford.

3.6 Nutrients in the upper waters

Time-series plots of DRP (Fig. 10A), NH₄-N (Fig. 10B), NO₃-N (Fig. 10C) and DON (Fig 10D), showed values within the seasonal range measured over the whole period of the present monitoring programme since 1994. DRP data have a mean concentration of 1.1 mg m⁻³ with a maximum value of 3.9 mg m⁻³ measured in winter 2005. This is the highest surface water concentration of DRP recorded during the present monitoring programme since 1994.

In earlier reports (e.g., Gibbs 2005), the changes in the surface water concentrations of NH₄-N and NO₃-N between 1996 and 2003 have been referred to as trends of decline following the changes that occurred at the time of the Mt. Ruapehu eruption in 1995. However, for the period from 2003 to 2005 (Figs. 10 & 11), the concentrations have been similar to those measured in the period prior to the Mount Ruapehu eruptions (Fig. 10).

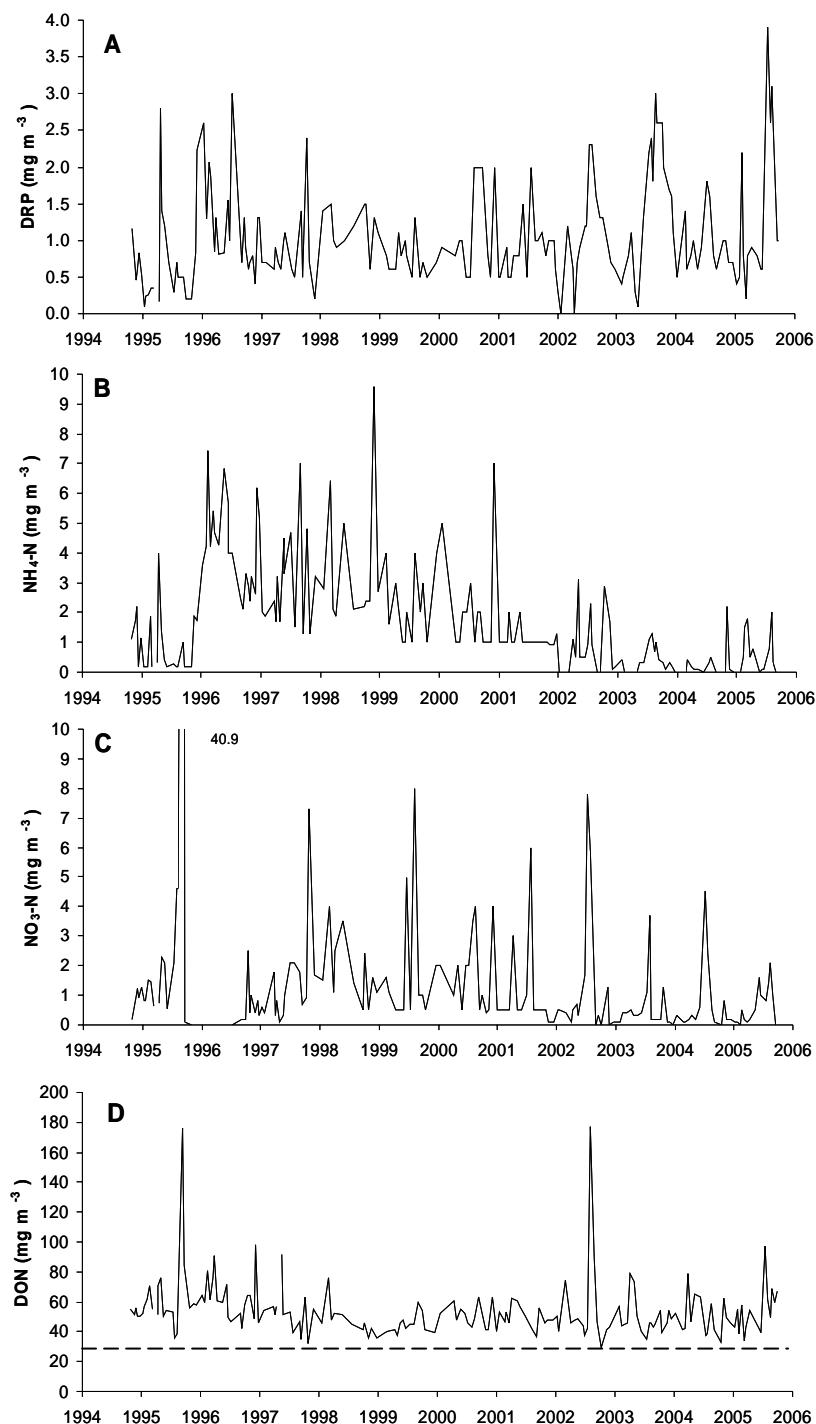

Figure 10: Time series data from the top 10 m of water column in Lake Taupo for (A) dissolved reactive phosphorus (DRP), (B) ammoniacal nitrogen ($\text{NH}_4\text{-N}$), (C) nitrate + nitrite nitrogen ($\text{NO}_3\text{-N}$), and (D) dissolved organic nitrogen (DON). Broken line indicates the minimum DON concentration as the background concentration of refractory organic material in the lake.

A peak in DON concentration was observed in July 2005 and was accompanied by a doubling of DOP (not shown) and the peak DRP concentration (Fig. 10). DON data had a mean concentration of 52 mg m^{-3} and there was no statistically significant trend in the data.

However, of some importance is the minimum DON concentration¹ of 29 mg m^{-3} . That a minimum should exist across a 12 year dataset implies that there is a refractory² component to the DON which presently accounts for more than half of the dissolved N in the upper water column of the lake in summer. This has formed the basis for a separate study by Hall et al. (2005).

Fluctuations in the surface $\text{NO}_3\text{-N}$ and DRP concentrations (Fig. 11) corresponded with winter mixed periods when nutrient enriched bottom waters (Fig. 12) were dispersed up through the lakes water column. It is of interest that following the surface increases in nutrients, $\text{NO}_3\text{-N}$ has consistently been rapidly reduced to very low (often undetectable) levels while the reduction in DRP has not been as great (Fig. 11). This sequence of timing is consistent with nitrogen limitation in the surface water. The fluctuations in $\text{NH}_4\text{-N}$ concentrations are often around the limit of analytical determination.

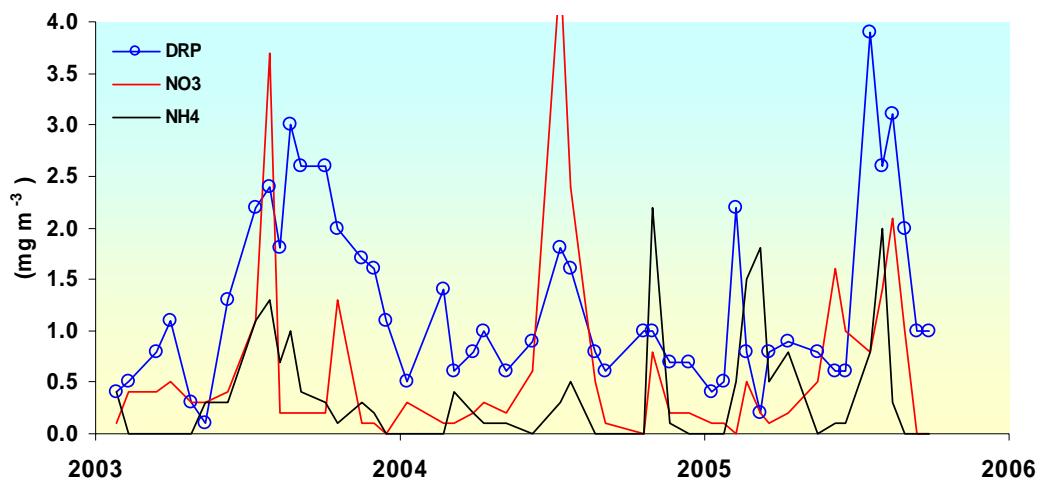

Figure 11: Time series data from the top 10 m of water column in Lake Taupo for dissolved reactive phosphorus (DRP), nitrate + nitrite nitrogen ($\text{NO}_3\text{-N}$) and ammoniacal nitrogen ($\text{NH}_4\text{-N}$) since January 2003. Maximum $\text{NO}_3\text{-N}$ value in 2004 was 4.5 mg m^{-3} .

¹ A transcription error in the DON data for 5 August 2000 has been found and corrected. Previous value 12 mg m^{-3} , actual value 43.5 mg m^{-3} .

² Resistant to breakdown

The low summer dissolved inorganic N (DIN) concentrations in the surface waters since 2003 (Fig. 11) coupled with the low chlorophyll *a* and high water clarity, suggest that phytoplankton have removed available N before summer. This is consistent with the presence of the summer deep chlorophyll *a* maximum just below the thermocline (Fig. 8B).

The proliferation of nitrogen fixing blue-green algae (e.g., *Anabaena flos-aquae*) in autumn since 2000 may be related to the availability of DRP in the surface waters and the lack of DIN to support other competing species of algae in the upper water column at that time.

3.7 Nutrient accumulation in the hypolimnion

Dissolved inorganic nutrients in water samples from 150 m demonstrated consistent seasonal patterns which more precisely determine the time of complete mixing in winter (Fig. 12). Winter mixing was indicated by the sudden drop in DRP and NO₃-N concentrations that usually occurs around the beginning of August.

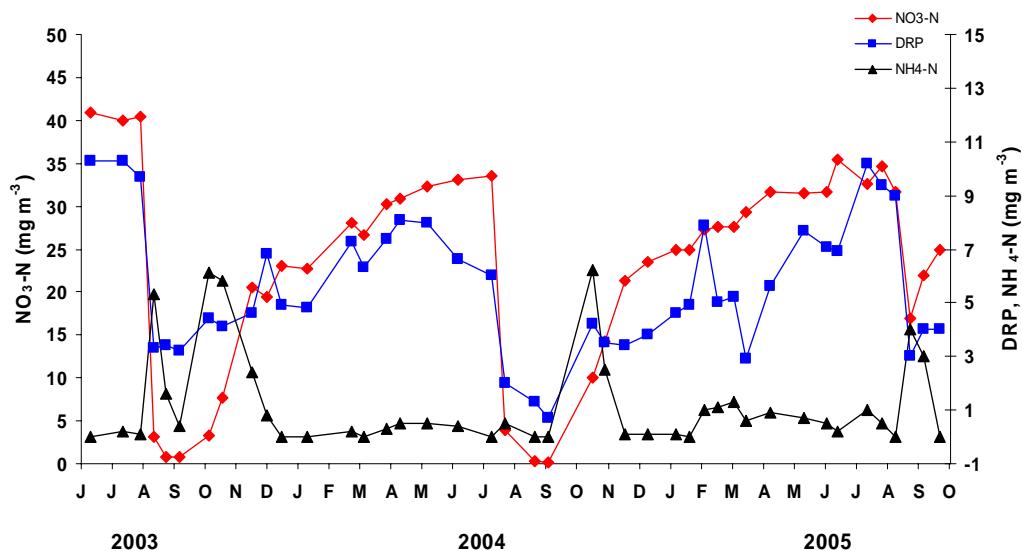

Figure 12: Time series data for DRP, NO₃-N and NH₄-N in the bottom waters of Lake Taupo since winter mixing 2003 inclusive.

As noted in earlier reports, there were small variations in the maximum DRP and NO₃-N concentrations reached before winter mixing, but the annual accumulation rates were similar between years. The NH₄-N data showed apparent pulses during the mixed period but these were variable in magnitude and period from year to year. The data showed that when the lake was completely mixed, DRP and NO₃-N

concentrations approached the limits of detectability (years 2003 and 2004). However, winter 2005 was different. Hypolimnetic DRP and $\text{NO}_3\text{-N}$ concentrations only dropped to half the concentrations recorded in autumn. This indicates that the lake was incompletely mixed. Coupled with the temperature data (Fig. 2A) which show that mixing was very brief, these data suggest that there was insufficient time for complete mixing in winter 2005. Consequently, half of the 2004-05 accumulation of DRP and $\text{NO}_3\text{-N}$ will carry over to the next year.

A consequence of incomplete mixing would be a reduced amount of DIN being mixed into the upper water column and a concomitant reduction in the algal biomass produced in the 2005 winter-spring bloom. This was seen in the chlorophyll *a* data (Fig. 7) and was a contributing factor to the higher than normal water clarity in winter 2005 (Figs. 5 & 6).

During the present monitoring programme since 1994, the annual accumulated mass of $\text{NO}_3\text{-N}$ in the hypolimnion³ before winter mixing has ranged from a low of around 200 t in 1996, steadily increasing to more than 600 t in 2000 (Fig. 13), and is presently around 400 t. The accumulated mass of DRP in the hypolimnion before winter mixing has followed the same pattern, rising from around 35 t in 1995 to more than 120 t in 2000, and is presently around 95 t. The mass of $\text{NO}_3\text{-N}$ and DRP in the hypolimnion before winter mixing has been relatively stable for the last 3 years.

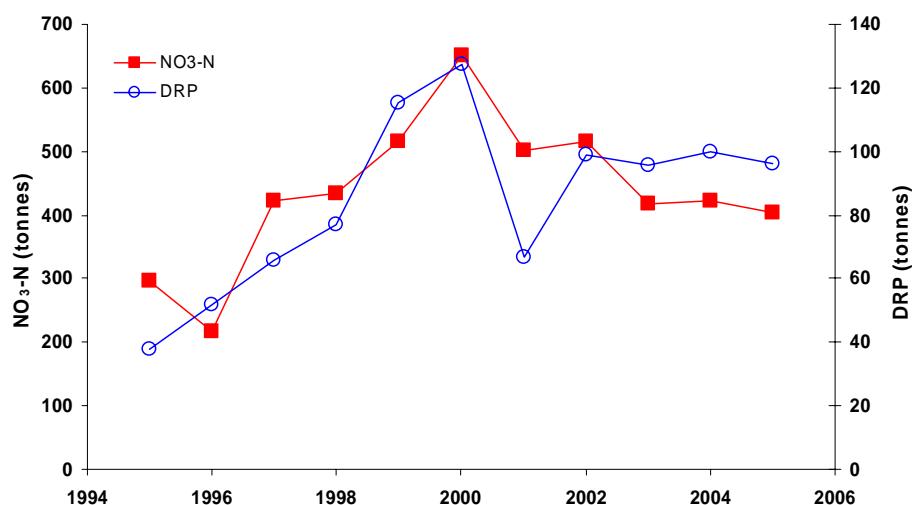

Figure 13: Total mass of $\text{NO}_3\text{-N}$ and DRP in the hypolimnion of Lake Taupo below 70 m in autumn before winter mixing. The ratio of N:P is around 4:1.

³ An error in the calculation of the accumulated mass of nitrate in the hypolimnion of Lake Taupo has been corrected in this report. The correction produced a small increase in the mass of nitrate accumulated but did not significantly affect the rate of increase of that accumulation (Figure 14).

Including the historical data since 1975⁴, there is a statistically significant ($P < 0.001$, $r^2 = 0.59$, $n = 17$) long-term trend of increase in the annual rate of $\text{NO}_3\text{-N}$ accumulation in the hypolimnion before winter mixing of around 11 t y^{-1} (Fig. 14).

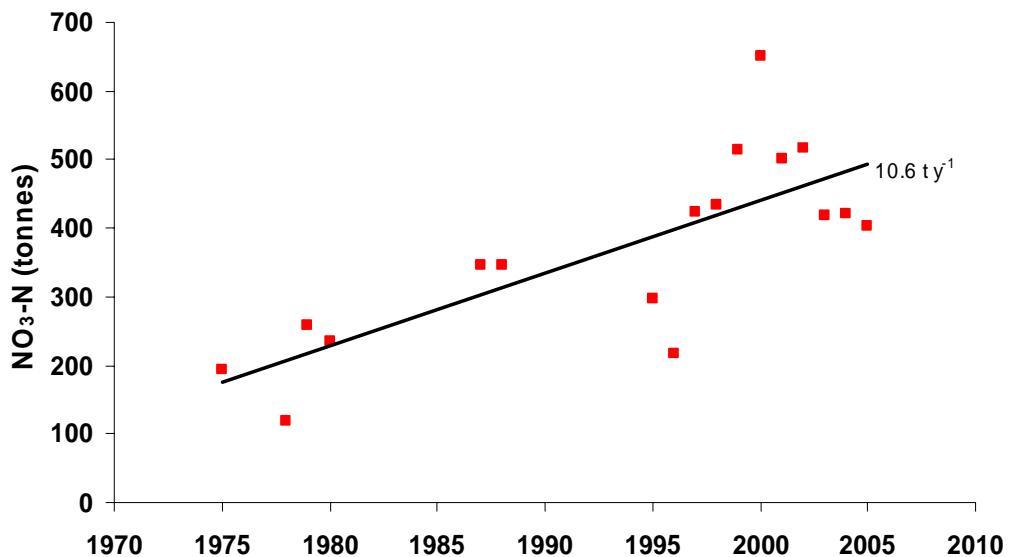

Figure 14: Long-term time series of total mass of $\text{NO}_3\text{-N}$ in the hypolimnion of Lake Taupo in autumn before winter mixing. The regression line indicates a statistically significant trend of increase in the rate of accumulation of around 11 t y^{-1} ($P < 0.001$, $r^2 = 0.59$, $n = 17$).

In contrast, there is no statistically significant trend in the long-term time-series data for total nitrogen (TN) based on spring profile data (Fig. 15). Although there is obvious interannual variability in the mass of TN in spring, after winter mixing, the total mass of TN in Lake Taupo remains at around 3300 t.

With an annual nitrogen input to Lake Taupo of around 1200 t (W. Vant, pers. comm.) and a theoretical mean residence time of water in Lake Taupo of 10.5 y, the lack of an apparent measurable increase in the mass of TN in the lake indicates that either the in-lake processes are “coping” with the annual load or that the timing of data collection used to assess the annual change in TN may be inappropriate. While the latter is possible, were a substantial proportion of the annual input of TN accumulating in the lake water column, it would be recorded. This implies that in-lake processes are removing the annual load of nitrogen from the water column either by sedimentation and subsequent burial or by microbial processes such as denitrification.

⁴ An error in the dates for the time-series data have been corrected in this report. Data plotted for autumn 1994 was actually from autumn 1988.

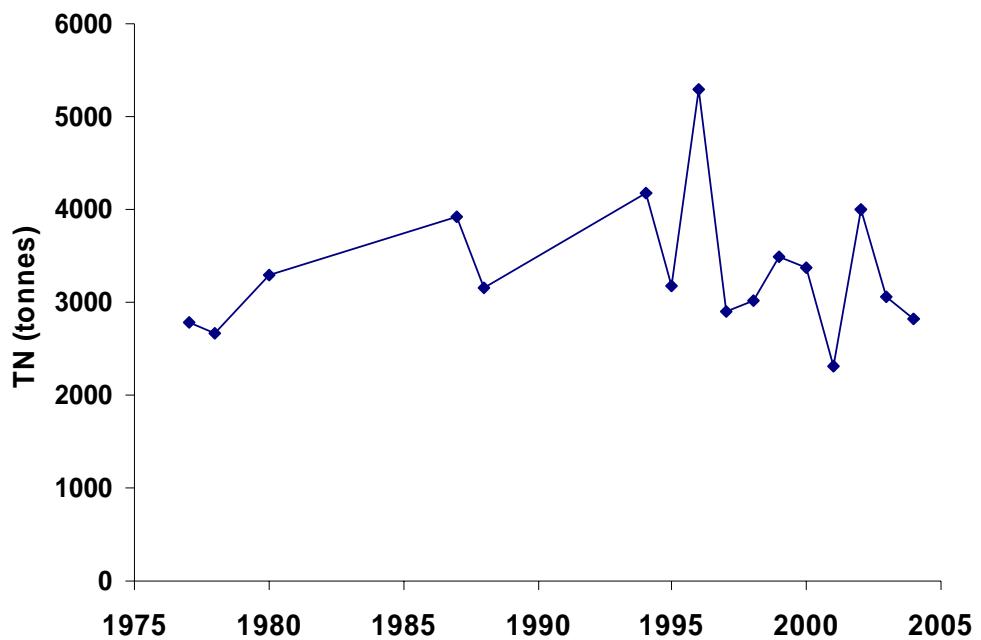

Figure 15: Long-term time series estimates of the mass of total nitrogen (TN) in Lake Taupo in spring after winter mixing. There is no statistically significant trend in the data. The mean of the mass is around 3300 t.

4. Knowledge gaps

There is little information on the in-lake processes in Lake Taupo, especially at the sediment-water interface. The TN data (Fig. 15) highlight an apparent anomaly that, despite an annual net input of TN of around 1200 t yr^{-1} , trends in the data suggest that the TN in the lake water column increased by less than 10 t yr^{-1} . How much of the annual net TN and TP input is buried or sequestered or transformed by microbial processes is unknown. Using the information collected in the long-term monitoring programme an estimate can be made of the potential magnitudes of some of these processes as follows:

With the strengthening inverse relationship between algal biomass and water clarity in recent years, it would be reasonable to assume that much of the nutrient release from the sediments and thus accumulation in the hypolimnion is derived from decomposition of sedimented algal biomass. However, because the N:P ratio of the inorganic nutrients released is around 4:1 (Fig. 13) rather than the stoichiometry of N:P in phytoplankton at about 8:1, it must be assumed that biological processes are preferentially removing N. The most likely microbial N removal process in the dark at the bottom of the lake would be denitrification in the sediments. Although no measurements of denitrification have been made in Lake Taupo, an extension of the above logic would suggest that about 75% of the nitrogen mineralised by decomposition processes may be denitrified. This could account for over 1000 t yr^{-1} . Unlike some of the other lakes of the Central Volcanic Plateau (e.g., L. Rotoiti), we know almost nothing about this process in Lake Taupo

To resolve these issues, measurements of in-lake processes are required on a seasonal basis to refine hydrodynamic and nutrient modelling of the lake. Specific information gaps include a current nutrient budget for the lake and a budget for the internal cycling processes such as: seasonal sedimentation rates, spatial and temporal sediment transformation and flux rates, inshore versus offshore processes, and the magnitude of any sublacustrine nutrient inputs associated with the hydrothermal venting through the lake bed.

5. Summary

- Phytoplankton biomass, as indicated by chlorophyll *a* concentration, continues to increase with a mean annual rate of $0.054 \pm 0.036 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P < 0.01$, $r^2 = 0.49$, $n = 12$) over the 11 year monitoring period.
- Winter chlorophyll *a* maximum concentrations are still increasing at more than twice the mean annual rate, although peak biomass in winter 2005 was less than on 2004 due to incomplete mixing in winter 2005.
- Since January 2003, there has been a strong inverse logarithmic relationship between chlorophyll *a* and water clarity ($P << 0.0001$, $r^2 = 0.69$, $n = 47$).
- Algal species dominance followed a succession from *Oocystis* and *Botryococcus* in summer, through *Cyclotella* and *Ceratium* in autumn to *Fragilaria* in winter 2004 but an *Asterionella* / *Aulacoseira* mixture in winter 2005. This succession of species is not unusual. Blue-green algae (*Anabaena flos-aquae*) became the dominant species for a brief period in May 2005 although they were present from March to June.
- The mass of $\text{NO}_3\text{-N}$ and DRP accumulating in the hypolimnion in autumn before winter mixing at around 400 t and 95 t, respectively is similar to the amounts that have accumulated in the last three years but is about twice the mass estimated at the beginning of the present monitoring programme since 1994.
- Incomplete mixing in winter 2005 only mixed about half of the accumulated nutrients from the bottom water to the surface waters. The remaining nutrients in the hypolimnion will be carried over to the 2005-06 stratified period.
- Including the historical data since 1975, there is a statistically significant ($P < 0.001$, $r^2 = 0.59$, $n = 17$) long-term trend of increase in the annual rate of $\text{NO}_3\text{-N}$ accumulation in the hypolimnion before winter mixing of around 11 t y^{-1} .
- The 2004/05 net VHOD rate for the whole period was $11.3 \pm 1.1 \text{ mg m}^{-3} \text{ d}^{-1}$ (mean \pm 95% confidence limit) was similar to the previous year at $11.5 \pm 2.8 \text{ mg m}^{-3} \text{ d}^{-1}$.

- The present VHOD values are now more than $2 \text{ mg m}^{-3} \text{ d}^{-1}$ higher than they were in 1994/95 and 1995/96.
- Nutrient concentrations (DRP, $\text{NH}_4\text{-N}$, and $\text{NO}_3\text{-N}$) in the upper water column were generally comparable with concentrations since 2003. DRP concentrations were consistently measurable, averaging 1.1 mg m^{-3} and peaking at 3.9 mg m^{-3} during winter mixing, 2005. Both $\text{NH}_4\text{-N}$, and $\text{NO}_3\text{-N}$ concentrations were approaching the limits of analytical detection for much of the year with brief increases in concentration at the time of winter mixing.
- New evaluation of the time-series for surface water $\text{NH}_4\text{-N}$, and $\text{NO}_3\text{-N}$ data over the monitoring period since 1994 suggests that the elevated concentrations found after the Mount Ruapehu eruptions have now returned to pre-eruption concentrations.
- DON data have a consistent minimum value of about 30 mg m^{-3} which indicates that more than half of the dissolved N in Lake Taupo in summer is refractory.
- Bottom water temperatures have risen to 11°C by winter 2005 after they fell from 11.6°C to 10.5°C during winter mixing 2004. This increase may reflect the brief and thus incomplete mixing in winter 2005.
- Water clarity, as indicated by Secchi disc depth data show a strong seasonal pattern with low clarity during the winter bloom and high clarity during summer. Since January 2003 the Secchi disc depth data have been strongly inversely proportional to chlorophyll *a* concentrations in the top 10 m.
- Unusually high water clarity in winter 2005 may be attributed to the relatively low winter algal biomass which followed the incomplete mixing of accumulated bottom water nutrients into the surface waters.

In a previous annual report (Gibbs et al. 2002), 3 trends in the data were identified — increasing phytoplankton biomass in the upper 10 m, increasing $\text{NO}_3\text{-N}$ mass in the lake hypolimnion prior to winter mixing, and an increasing range in the variability of water clarity — that were of concern with respect to the water quality of Lake Taupo. These trends in the data are still present.

6. Acknowledgments

This report was made possible by the team effort of Les Porter, Brent McIntosh and Jill Cogswell of the Taupo Harbourmaster's Office, and Eddie Bowman (NIWA Rotorua) who have collected the data. Much of the success of this monitoring programme is attributable to the extra effort by Eddie and the team. The efforts of Nick Bradford of Taupo in watching for, and providing an early warning of, the appearance of cyanophytes in the inshore waters of the lake are very much appreciated.

Water samples were processed in the NIWA chemistry laboratory and analytical results were provided by Graham Bryers, Denise Rendle, Stu Pickmere and team. Quality control was provided by Mike Crump, Lab Manager.

Phytoplankton dominance and enumeration results were provided by Karl Safi.

8. Appendix 1. Site map, sampling strategy and methods

The following section has been copied from Gibbs 1995, and modified after 1998.

Site Map

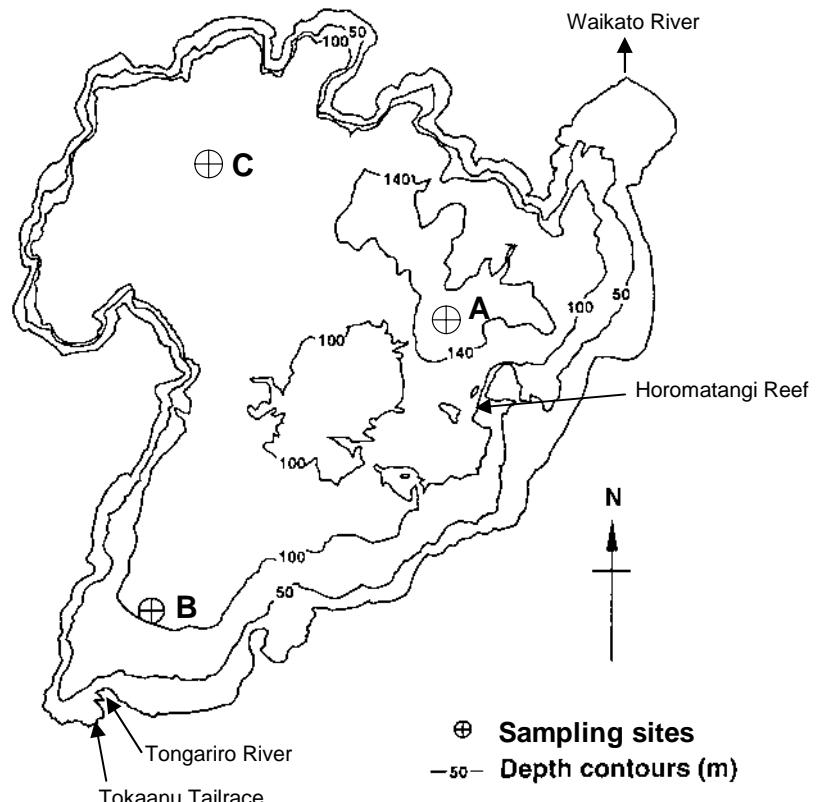

Figure 1: Site map of Lake Taupo showing location of the routine monitoring site at mid-lake (A). Two additional sites at Kuratau Basin (B) and the Western Bays (C) were sampled between January 2002 and December 2004 inclusive. Data from those sites have been retained with the Site A data presented in the appendices.

8.1 Methods

The sampling site was selected in the central basin of Lake Taupo (Site Map) with a water depth of about 160 m. This site is more than 5 km from the nearest land and is exposed to both the north-south and east-west axis of the lake.

To calculate VHOD requires two measurements each year far enough apart in time for a measurable change to occur in the DO concentrations in the hypolimnion of the lake. Details of the procedure and limitations of this measurement are described by Vant (1987). For the monitoring of Lake Taupo, which mixes briefly in winter between July and August, the initial sampling time was selected to be in October, to give sufficient time for thermal stratification to establish a stable hypolimnion. The final sampling time was selected to be in April, before lake cooling causes the downward movement of the thermocline which precedes the winter mixing.

At each of these biannual samplings, a detailed profile of DO and temperature was measured. Prior to 1998, measurements were made at 1 m depth intervals through the full depth of the water column using an *in situ* recording Applied Microsystems STD-12 profiler fitted with a Royce DO sensor, and compared with manual measurements of DO and temperature made at 10 m depth intervals from the surface to the bottom of the lake using a Yellow Springs Instrument (YSI) model 58 dissolved oxygen meter fitted with a stirred Model 5739 probe on a 160 m cable. Subsequent to 1998, a Richard Brancker Research (RBR) model TD410 conductivity-temperature-depth (CTD) profiler fitted with a stirred YSI model 5739 DO sensor was used. In January 2002, the TD410 CTD profiler was upgraded to an RBR model XR420f freshwater CTD profiler fitted with the YSI model 5739 DO sensor and a Seapoint chlorophyll fluorescence probe. The DO sensor was calibrated regularly by NIWA, Rotorua staff and chlorophyll fluorescence was converted to chlorophyll *a* from extracted chlorophyll *a* analyses of water samples collected beside profiler.

The following parameters were also measured as profiles from water samples collected using a van Dorn water sampling bottle starting at 1 m and then at 10 m intervals from 10 m to the bottom of the lake:

DO, chlorophyll *a*, dissolved reactive phosphorus (DRP), dissolved organic phosphorus (DOP), particulate phosphorus (PP), total phosphorus (TP), nitrate + nitrite nitrogen* ($\text{NO}_3\text{-N}$), ammoniacal nitrogen ($\text{NH}_4\text{-N}$), dissolved organic nitrogen (DON), particulate nitrogen (PN), total nitrogen (TN), urea nitrogen (Urea-N), total suspended solids (SS), volatile suspended solids (VSS), particulate carbon (PC),

dissolved organic carbon (DOC), and water colour. (* Little, if any nitrite is ever found in the Lake Taupo water column, hence the use of NO₃-N).

Note: TN and TP values are the summation of all other N and P components, respectively, excluding Urea-N which is part of the DON component.

Additional parameters measured but not as complete profiles were:

Water clarity (by Secchi disc depth) and algal species composition and abundance on water samples from 1, 10, 50, 100, and 140 m.

Determinations on the water samples were made with the standard methods routinely used for freshwater analysis by NIWA.

Data for the low level monitoring programme were scheduled to be collected from the mid-lake sampling station at 2 weekly intervals. The practicality of achieving this target was limited by the weather and in reality data were generally collected at about 2-3 weekly intervals. Parameters measured were:

DO and temperature profiles at 1 m depth intervals to the bottom of the lake by RBR XR420f profiler, water clarity as Secchi disc depth, and a 10 m tube water sample was collected for measurement of chlorophyll *a*, NO₃-N, NH₄-N, TN, DRP, TP, and algal species dominance.

Near-bottom water samples from 150 m were collected using a van Dorn water sampling bottle and analysed for DRP, NO₃-N, and NH₄-N.

8.2 Data handling and less than detection limit values

All data in this report have been processed and manipulated on Excel spreadsheets. Data is rounded using the Excel protocol to an appropriate number of significant numbers based on the need for detailed knowledge tempered with the confidence in the precision and accuracy of the analytical methods used. This treatment may lead to small differences between electronic copies of the data and the values presented in this report.

The difference between the written report and the Excel spreadsheet of essentially the same data is the treatment of the less than detection limit (<DL) results. The data have

in the past been written as <DL or <DL(value). For statistical analysis the excel spreadsheet replaces <DL with 0 or uses the value in brackets in place of 0. Although it is recognised that the former action will be in error, the use of the value in brackets requires some justification.

In discussion with Burns Macaskill, Graham McBride, and Mike Crump from NIWA on this issue, the following conclusions were reached:

- In general the data is reported as a series of results from analytical methods which have known limitations and precision. The raw number is reported were ever possible so that the user can draw their own conclusions about the reliability of the "last significant figure" on any result when performing data manipulations.
- The real problem arises at very low levels and the result obtained is less than the method's prescribed DL. The problem is not so much the result obtained but what to do with it which in turn raises the question 'What do we mean by detection limit'?
- In the book "Statistical methods in water resources" Helsel & Hirsch 1992 [Studies in Environmental Science 49, Elsevier], and chapter 13 "Methods for data below the reporting limit" it is pointed out that the 'detection limit' is variously known as the 'reporting limit' or the 'limit of quantitation'. If no other value is available, there are 3 main options: call it zero (which is clearly an under estimate), call it the detection limit (which is clearly an over estimate), or call it half the detection limit (which gives a 50:50 chance of an over or under estimate). The choice then is one of 'which convention do you wish to use. In the written reports, I have treated the <DL as zero for summation purposes. This is an under estimate which I should have noted on each report page so that anyone using that data is aware of the convention used.
- An alternative approach is to say that, before the sample is analysed, the DL is the ***predicted minimum*** level that will be found using the stipulated method. However, once the sample is analysed the result is what was ***actually measured*** and may be <DL on the day of analysis. As it is an actual analytical result, that value (reported in brackets) should be reported even though it is <DL. This implies that the method DL is in reality a reporting level or level of confidence.

- The "DL" was derived for the Lake Taupo data, on each analytical occasion, from a series of blanks and 1ppb standards run with the samples. The "DL" is set as 3 times the SD of the 1 ppb standard. This is actually a limit of confidence. All samples are run in duplicate and the mean of the two results becomes the concentration reported.

- With the introduction of the Lachet FIA system, the limits of detection have been confidently pushed to the point where replicate results may often be <DL. In these instances, in the written report, the value is reported as <DL(result). In the past I have still used the <DL = 0 convention in summation for the TN and TP data. This is obviously wrong and the actual result should be used, as is done in the electronic spreadsheet.

In this report the analytical value ‘on-the-day’ has been used wherever possible. Data reported as <DL use the <DL = DL/2 convention. Past data have not been corrected or altered to conform to this protocol.

These technical details are incorporated in this annual report so that data users are aware of how the 'DL' or confidence limit was set and how the values <DL are treated when performing data manipulations.

There is still the question of how to deal with numbers where the result has been simply reported as <DL. The use of the DL/2 convention is probably closer to reality than the DL = 0 convention.

Helsel & Hirsch suggest an alternative method for estimating a value in the <DL range. If there is sufficient real data >DL, a probability curve can be derived and extrapolated around the DL to generate the most probable number for the <DL value.

8.3 Statistical methods

Copied from Gibbs (2000b).

In this report we have used linear regressions and associated statistical tests to examine trends. The key result of these procedures is the coefficient of determination (r^2), which measures the amount of variability in the data that is accounted for by the

regression. Another is the P -value.⁵ This can be used as a weight of evidence against the hypothesis that there was in fact no trend. This weight is strong when P is small, meaning that a trend at least as large as that measured could have occurred merely by chance—we have only a limited number of data from which to infer the strength of any trend, so our measurements always are uncertain to some degree. So if P is low enough (taken as less than 5% in this report, which is the usual practice), it is conventional to say that the measured trend is "statistically significant", and that convention is followed in this report. However, it is important (and often not realised) to note that the P -value cannot be used as an *absolute* weight of evidence. This is because it tends to decrease as the number of samples taken in a given period is increased. For example, when we plot monthly Secchi disc depth data from 1994–2001 (Figure 3A, Gibbs 2000b) with these 93 data we obtain a statistically significant result (because $P < 0.05$)—even though the coefficient of determination was only $r^2 = 0.0445$. When we plot the minimum winter clarity over this period we then have only 7 data. In this case (Fig. 3B, Gibbs 2000b) we happen to have the same measured trend slope with a much higher coefficient of determination ($r^2 = 0.464$), yet the result is *not* statistically significant (because $P = 0.09$). This is entirely because of the reduced number of samples in the winter minimum case. What this makes clear is that the P value is useful as a *relative* weight of evidence when comparing datasets of the *same size*, but it has no evidential meaning when comparing results from datasets of very different sizes.

⁵ It is defined as the probability of obtaining a trend at least as extreme as was obtained if in fact there was no trend at all.

9. Appendix 2. The calculation of net VHOD rates

Copied from Gibbs 1995.

Rationale

In the strictest terms, VHOD can only be calculated for a lake which has thermally stratified and the resultant thermocline provides an effective barrier against re-oxygenation of the hypolimnion. The measure of the barrier efficiency is the rate of heating of the hypolimnion following stratification as heat will be transferred across the thermocline at a similar rate to oxygen.

In Lake Taupo, the thermal inertia of the hypolimnion is so great that heating during the stratified period is typically about 0.2 °C and never more than 0.4 °C over a 200 day period. While this would seem to meet the temperature criterion, in a lake that large, oxygen can be transferred into the hypolimnion by mechanisms other than diffusion.

Wind induced mixing may increase turbulent diffusion across the thermocline as would an internal seiche on the thermocline. Both of these mechanisms would also transfer heat. The penetration of the thermocline by an underflowing density current would entrain oxygenated surface water into the hypolimnion with that flow. As the density current must be colder than the thermocline to plunge through it, there is no heat transferred with this mechanism.

In Lake Taupo the Tongariro River is always colder than the surface water and for at least 9 months of the year it is also colder than the minimum lake water temperature of 10.3 °C. Thus, during most of the stratified period, the Tongariro River flows directly into the hypolimnion entraining oxygenated surface water with it. The amount of surface water entrained has been estimated to be about 10 times the river discharge. The amount of oxygen transported in this way is likely to be more than 200 tonnes per day (Gibbs 1996).

Clearly this is a substantial oxygen input which invalidates the concept of the thermocline forming an oxygen barrier for purposes of calculating the VHOD. The true VHOD may only be calculated during mid summer when the Tongariro River flows deep into the epilimnion but does not penetrate the thermocline.

The data collected to date indicates that hypolimnetic oxygen depletion occurs throughout the stratified period - with or without the density current re-oxygenation - and hence the value obtained from a VHOD calculation over the whole stratified period is the net VHOD rate taking all the factors affecting the hypolimnion into account.

As the data from 1996/97 shows the density current also advects dissolved organic nutrients with it, management strategies which affect the Tongariro River also impact on the lake. Hence it is appropriate to use the net VHOD rate for interannual comparisons rather than the true or gross VHOD rate calculated only through mid summer.

Method of calculation

The following is the method used to calculate the net VHOD rate for Lake Taupo.

Requirements: Microsoft EXCEL spreadsheet or equivalent.

EASY PLOT statistical graphing package or equivalent.

Although the thermocline in Lake Taupo is usually at about 40 m, the isothermal water column lies below 70 m. To accommodate the gradient across the thermocline, the net VHOD rate calculation only uses oxygen data from below 70 m.

To calculate the mean oxygen concentration in the water column below 70 m, the DO concentration at each 10 m depth increment is multiplied by the volume of the 10 m slice it came from. This assumes rapid horizontal mixing and minimal vertical mixing to extrapolate one DO value across the whole lake. Historical data from multiple sites would suggest that this is a reasonable assumption.

The slice volumes (hypsographic volumes) for Lake Taupo have been calculated for 10 m thick layers centred on the 5 m point of each slice i.e., 75, 85, 95, 105 m etc. The DO measurements are made at 10 m intervals i.e., 70, 80, 90, 100, 110 m etc.

The mass of oxygen in each 10 m slice is the average of the DO concentration at the top and bottom of a slice multiplied by the slice volume. i.e., for the 70 - 80 m slice the calculation is:-

$$\text{mass}_{70-80m} = ((\text{DO}_{70m} + \text{DO}_{80m}) \div 2) \times \text{Volume}_{70-80m}$$

For each profile date:

Compute the mass for each 10 m slice between 70 m and 150 m and sum the results as the total mass of DO in the hypolimnion below 70 m. Sum the slice volumes below 70 m as the total volume of the hypolimnion below 70 m.

The volume weighted mean DO concentration is the total mass value divided by the total volume value.

Use the sequential day number or equivalent to construct a time series of volume weighted mean DO concentrations over the stratified period and use the CURVE FIT regression analysis of EASY PLOT to obtain the $y = ax + b$ straight line fit for these data.

As the DO data are in g m^{-3} , the value of 'a' is in $\text{g m}^{-3} \text{ d}^{-1}$. Divide 'a' by 1000 to get the net VHOD rate in $\text{mg m}^{-3} \text{ d}^{-1}$. The negative sign indicates a loss rate.

The hypsographic volumes and upper surface areas of the 10 m slices through the whole depth of Lake Taupo are listed at the end of this section.

Lake Taupo Hypsographic Data used in the Net VHOD RATE calculation.

Slice depths (m)	Volume of slice (km^3)	Upper surface area of slice (km^2)
0 - 10	5.849359	600
10 - 20	5.599702	570

Statistical evaluation of the VHOD rate

From the 1999-2000 monitoring report (Gibbs 2000b), the VHOD rate is expressed as the calculated net VHOD rate \pm the 95% confidence limit. This gives a meaningful estimate of the range within which the VHOD rate lies and is more appropriate than the standard deviation on the data or a standard error estimate on the regression coefficient.

Julian Date or sequential day number for each day of the year.

10. Appendix 3. Temperature and dissolved Oxygen data

Includes accumulated data since 1994.

* represents data missing or invalid.

For completeness, additional data from the Kuratau Basin (site B) and Western Bays (site C) collected for the period between January 2002 and December 2004 are included as separate sheets following the mid-lake data from site A for those years.

Lake Taupo Temperature, Dissolved Oxygen, and Secchi Depth Database.
Mid-Lake site A for the period starting 24 August 2004

2004-2005

11. Appendix 4. Nutrient data

Includes accumulated data since 1994. Blank cells represent missing data.

For completeness, data collected from the Kuratau Basin (site B) and Western Bays (site C) from January 2002 to December 2004 are included as separate sheets following the mid-lake data from site A for those years.

In the spring/autumn profile data, two different analytical methods are used to measure particulate nitrogen: (1) A wet digestion method involving high temperature refluxing in digestion mixture [persulphate / sulphuric acid / Selenium catalyst] for 3 hours followed by colorimetric determination of the nitrogen as the ammoniacal form, and (2) a CHN combustion method which converts all nitrogen compounds to N₂ gas in a furnace at ~1000°C to be measured in a thermal conductivity detector.

Particulate nitrogen analysed by the wet digestion method may not include some refractory nitrogen components which may be detected by the CHN combustion furnace method. Consequently the PN value from the CHN combustion furnace method should always be greater than or equal to the PN value obtained by the wet digestion method. Occasionally they are reported as less than the wet digestion method value in which case the wet digestion value should be regarded as correct. The cause of this difference is unknown but may be associated with the presence of low molecular weight organic nitrogen compounds lost during the drying step before combustion. The PN values for the time series data are all from wet digestion method analyses and hence are directly comparable with the profile data.

Low level NH₄-N results are likely to be subject to interference from low molecular weight DON and hence may not be biologically available for phytoplankton growth.

From February 2002, DRP, NO₃-N, and NH₄-N were measured on a Lachat Flow Injection Analysis (FIA) system but using essentially the same chemistry as previously used on the Technical Auto-Analyzer system. The reported detection limits for these nutrients remains the same at 0.5 mg m⁻³ for DRP and NO₃-N, and 1 mg m⁻³ for NH₄-N, however, the greater precision of the FIA system provides confidence in reporting results to a lower level as an indication of likely absolute values near zero. Such values are provided as an indication only and the true value should be expressed as less than the detection limit. TN and TP values are the sum of all other N and P components, excluding Urea-N which is part of the DON component. All analytical values ‘on-the-day’ are used wherever possible or <DL = DL/2 for summation.

The DON value for 5/08/2000 was corrected from 12 to 43.5 in March 2006. This was a transcription error from the original analytical result sheet.

Lake Taupo cumulative database of 10m tube sample data from October 1994 to September 2002.
Samples collected from central lake site.

 NH₄, NO₃, DON, Urea all as N

 Detection limits: DRP 0.5; NO₃-N 0.5; NH₄-N 1.0 mg m⁻³

New Analytical instrument (Flow Injection Analysis) from January 2002, gives greatly improved resolution at low levels.

 FIA instrument results are given as a better indication of likely absolute low levels of DRP, NO₃-N, and NH₄-N below nominal detection limit.

 NH₄, NO₃, DON, Urea all as N

 Detection limits: DRP 0.5; NO₃-N 0.5; NH₄-N 1.0 mg m⁻³

New Analytical instrument (Flow Injection Analysis) from January 2002, gives greatly improved resolution at low levels.

 FIA instrument results are given as a better indication of likely absolute low levels of DRP, NO₃-N, and NH₄-N below nominal detection limit.

 NH₄, NO₃, DON, Urea all as N

* = PN by wet digestion method, ** = PN by combustion furnace method.

 Detection limits: DRP 0.5; NO₃-N 0.5; NH₄-N 1.0 mg m⁻³

New Analytical instrument (Flow Injection Analysis) from January 2002, gives greatly improved resolution at low levels.
 FIA instrument results are given for Autumn as an indication of likely absolute low levels of DRP, NO₃-N, and NH₄-N.

Surficial sediment

* = Sediment contamination, sample not filtered for analysis.

 Detection limits: DRP 0.5; NO₃-N 0.5; NH₄-N 1.0 mg m⁻³

* = analysed by wet digestion method, ** = analysed by CHN combustion furnace method.

12. Appendix 5. Phytoplankton data

(Note: totals may vary by 1 due to rounding).

Remaining algal dominance counts from the 3-site measurements from 2002 to 2004 are included with these data.
