Executive Summary

With the expectation that the trophic status of Lake Taupo will slowly change to reflect changes in land use within the lake's catchments, a long term programme monitoring the lake's water quality was commissioned by Environment Waikato. This programme commenced in October 1994 and is conducted by NIWA with field assistance from the Department of Internal Affairs, Taupo Harbourmaster's Office.

The monitoring programme was designed to detect change through assessment of the rate of consumption of oxygen from the bottom waters of the lake (volumetric hypolimnetic oxygen depletion – VHOD) as an integration of all biological processes occurring in Lake Taupo. Additional parameters are measured to provide a more comprehensive picture of water quality. Recently it has become apparent that VHOD may be too coarse to determine trophic change in a lake the size and complexity of Lake Taupo. Consequently, more emphasis is now focused on the parameters 'phytoplankton biomass', 'water clarity', and nutrient (particularly nitrate) accumulation in the lake. This report presents the results from the 2006/07 monitoring period at the mid-lake site, Site A. Monitoring of additional sites in the Kuratau Basin (Site B) and the Western Bays (Site C) between January 2002 and December 2004 determined that spatial variability of water quality across Lake Taupo is minimal and that it is valid to use the mid-lake site as representative of the open water quality of the lake.

There is a trend of increasing phytoplankton biomass (chlorophyll *a*) in the upper 10 m of water column over the monitoring period of $0.04 \pm 0.03 \text{ mg m}^{-3} \text{ y}^{-1}$ with maximum chlorophyll *a* concentrations in winter 2006, at 2.8 mg m^{-3} , being higher than in most previous winter bloom periods. Regression analysis of maximum winter-spring chlorophyll *a* concentrations suggests that these have been increasing by $0.12 \pm 0.06 \text{ mg m}^{-3} \text{ y}^{-1}$ since the start of this monitoring programme in 1994. However, this trend may not be linear and concentrations may have reached a plateau. Before 2000, mean winter chlorophyll *a* maximum concentrations were 1.46 mg m^{-3} with an increasing trend of $0.18 \text{ mg m}^{-3} \text{ y}^{-1}$. After 2000, mean winter chlorophyll *a* maximum concentrations were 2.5 mg m^{-3} with no statistically significant trend or substantial change in the concentration data.

Highest biomass occurred in August when the lake had mixed and lowest biomass occurred in the upper water column in early summer when that winter biomass peak had sedimented from the water column. Chlorophyll fluorescence profiles show that, each year, a deep chlorophyll maximum (DCM) develops just below the thermocline (40 m) during summer and has up to 70% higher biomass¹ than the upper water column. The 2006 winter bloom was dominated by the diatom *Aulacoseira granulata*, with *Dinobryon* and *Botryococcus braunii* becoming dominant in summer and autumn 2007. Blue-green algae (cyanobacteria) were always present in low numbers in the upper water column throughout the 2006/2007 monitoring period, with *Anabaena lemmermannii* reaching a dominance

¹ Assuming a constant chlorophyll-fluorescence:biomass ratio

level of 3 on one occasion in March 2007. Algae collected from the DCM in April 2006 were dominated by dinoflagellates, *Dinobryon* and *Gymnodinium* sp.

Nutrient concentrations (DRP, NH₄-N, and NO₃-N) in the upper water column were comparable with concentrations measured since 2003, apart from high NO₃-N concentrations during winter mixing in 2006. With the development of the winter-spring bloom, all biologically available nitrogen, including labile DON, disappeared from the upper water column suggesting that phytoplankton growth was N-limited at that time. Subsequent appearance of NH₄-N in the upper water column through summer and autumn 2007 may indicate water column decomposition of the winter-spring bloom.

The total mass of NO₃-N in the hypolimnion before winter has increased at a statistically significant rate of about 8.4 t y⁻¹ ($P < 0.002$, $r^2 = 0.41$, $n = 20$) over the last 32 years. The net accumulation rate of NO₃-N in the hypolimnion below 70 m in 2006/2007 was 1.78 t d⁻¹. Regression analysis showed that there has been a weakly significant increase in the net NO₃-N accumulation rate of 0.03 t d⁻¹ yr⁻¹ ($P < 0.1$, $r^2 = 0.145$, $n = 20$) over the last 32 years.

Summer water clarity was similar to the previous year with Secchi depth values of 16 to 19 m. However, this level of clarity continued through most of autumn 2007 with a value of 18.5 m recorded as late as 27 June 2007. Water clarity in winter 2006 was 11 m in keeping with the high winter-spring algal biomass.

Water clarity data available through spring and early summer 2007/2008 showed an extended period with values greater than 20 m and a maximum value of 25 m, which is the highest clarity recorded for Lake Taupo. This extreme clear-water phase coincided with a drought (declared officially) and thus may reflect the reduced surface runoff and rain water input of nutrients as well as a low input of sediment from erosion.

The 2006/07 net VHOD rate at $10.73 \pm 2.45 \text{ mg m}^{-3} \text{ d}^{-1}$ (mean \pm 95% confidence limit) was about 1 mg m⁻³ d⁻¹ higher than the previous year which was $9.56 \pm 2.24 \text{ mg m}^{-3} \text{ d}^{-1}$.

In the 2002 review of the long-term monitoring programme data, 3 trends in the data were identified — increasing phytoplankton biomass² in the upper 10 m, increasing NO₃-N mass in the hypolimnion prior to winter mixing, and an increasing range in the variability of water clarity — that were of concern with respect to the water quality of Lake Taupo. In the previous report, it was also shown that the net accumulation rate of NO₃-N in the hypolimnion during the stratified period has increased over the last 30 years although the trend is not strong. These trends are still present in the data.

² Inferred from the chlorophyll *a* data and assuming the chlorophyll:biomass ratio is constant.

Glossary

BOD	Biochemical Oxygen Demand: the rate of oxygen consumption associated with biological decomposition and chemical processes and in the water column.
VHOD	Volumetric Hypolimnetic Oxygen Depletion: the net rate of oxygen loss associated with biological and chemical processes in the hypolimnion of a lake in the absence of a temperature change
Phytoplankton	Microscopic free-floating aquatic plants (algae)
Cyanobacteria	Blue-green algae. These are potentially toxic. They can adjust their depth in the water column using small gas bladders (gas vacuoles), and some species can use (i.e., fix) atmospheric nitrogen for growth when nutrient nitrogen in the water column is depleted.
Zooplankton	Small to microscopic free-swimming aquatic animals which graze on phytoplankton or smaller zooplankton
Biomass	The living mass of the phytoplankton or zooplankton populations
Thermal stratification	Separation of a water column into two layers by temperature – warmer water on top
Thermocline	The boundary zone or temperature gradient between the two layers in a thermally stratified water column.
Epilimnion	The upper water column in a thermally stratified water column
Hypolimnion	The lower water column in a thermally stratified water column
Metalimnion	The thermocline zone — of variable thickness
Euphotic zone	The upper water column in which there is sufficient light for photosynthesis and hence phytoplankton growth.
Euphotic depth	Lower limit of phytoplankton growth where light levels are 1% of surface irradiance
Nutrients	Essential dissolved inorganic nitrogen and phosphorus compounds which can be used directly by plants for growth
Ammoniacal nitrogen	Sum of ammonium ion (NH_4^+) plus free (unionised) ammonia (NH_3). Some amines (NH_2^-) may be included as interference during analysis. Symbol, $\text{NH}_4\text{-N}$.
Nitrate nitrogen	Used in this report as the sum of nitrate (NO_3^-) plus nitrite (NO_2^-). Symbol, $\text{NO}_3\text{-N}$.
DIN	Dissolved Inorganic Nitrogen: the sum of $\text{NH}_4\text{-N} + \text{NO}_3\text{-N}$
DON	Dissolved Organic Nitrogen: the soluble nitrogen other than DIN
PN	Particulate Nitrogen: includes phytoplankton and other detritus
TN	Total Nitrogen: Sum of DIN + DON + PN
NO_x	Gaseous oxides of nitrogen, including N_2O , NO , NO_2

1. Introduction

With the expectation that the trophic status of Lake Taupo will slowly change to reflect changes in land use within the lake's catchment, a long term monitoring programme of the lake's water quality was commissioned by Environment Waikato. This programme commenced in October 1994 and is conducted by NIWA with field assistance from the Department of Internal Affairs, Taupo Harbourmaster's Office. The monitoring precision was augmented from February 1999 by the use of a new profiling instrument – a Richard Brancker Research model RBR410 conductivity-temperature-depth (CTD) profiler/logger fitted with a Yellow Springs Instrument (YSI) model 5739 dissolved oxygen (DO) probe. In January 2002, this instrument was upgraded to a Richard Brancker Research model XR420f freshwater profiler/logger with improved sensitivity. The new profiler is fitted with a YSI model 5739 DO probe as well as a Sea Point Chlorophyll Fluorometer to give *in situ* estimates of vertical distribution of algal biomass within the lake water column. This report presents data from the routine mid-lake monitoring station from September 2006 to August 2007.

In two previous reports, data was included from two additional sites representing those historically measured in the 1974-76 assessment of lake water quality (White et al. 1980) (Fig.1) to evaluate spatial variability of water quality across the lake. Results from these additional sites showed that, in general, there was minimal variation between the sites, and that data collected from site A (mid lake) could be used as being representative of the main body of the lake. This report presents data from site A only.

The monitoring programme has 3 components: bottom water oxygen depletion, upper water column water quality, and whole water column water quality. Bottom water oxygen depletion is estimated as the volumetric hypolimnetic oxygen depletion (VHOD) rate, which is sensitive to changes in trophic status of lakes that thermally stratify for part of the year (Burns 1995). VHOD was chosen as the parameter most likely to detect a change in the water quality of Lake Taupo. Estimates of VHOD are made from dissolved oxygen and temperature profiles measured at 2-3 week intervals during the stratified period. However, the VHOD rate will only indicate that a change has occurred and will not detect other indicators of changing water quality. For that purpose, the upper water column is sampled for nutrients, chlorophyll *a*, phytoplankton species composition and water clarity at 2-3 weekly intervals, and the whole lake water quality is estimated from full profiles which are made twice during the stratified period. The first profile is in spring, when thermal stratification has become established and is stable. The second is in autumn the following year before thermal stratification begins to break down, and the thermocline deepens. Actual sampling dates are given with the results.

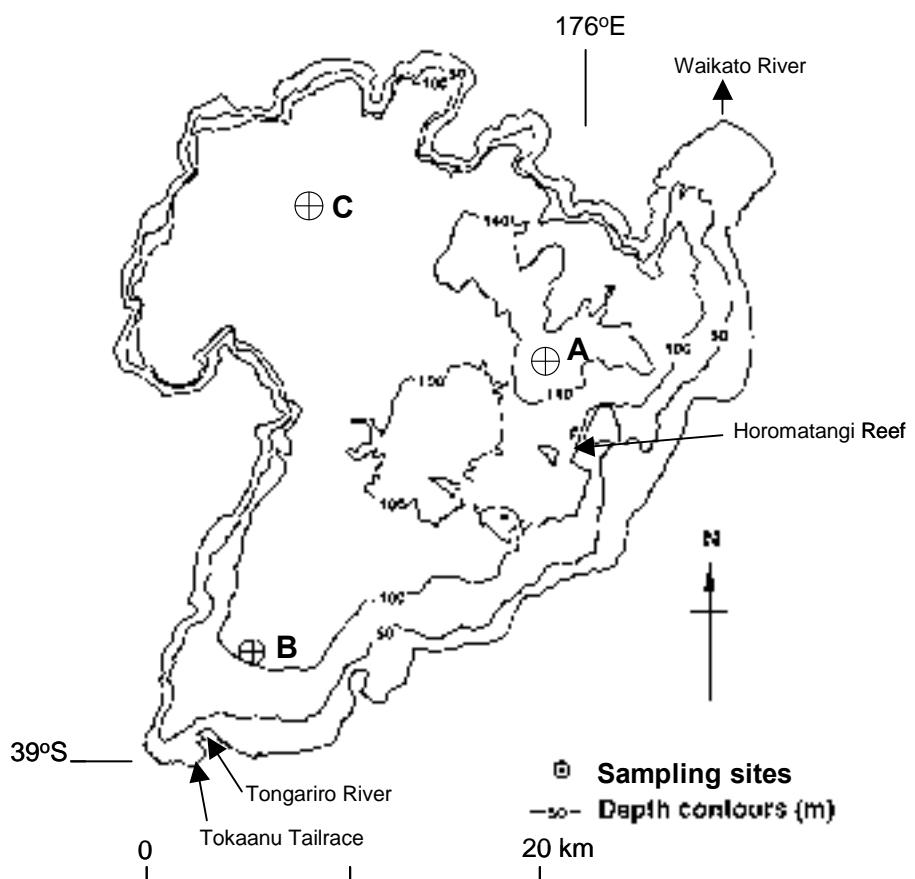

Figure 1: Site map of Lake Taupo showing location of the routine monitoring site at mid-lake (A), and the two additional sites at Kuratau Basin (B) and the Western Bays (C) sampled during the three-year period 2002-04. The generally close agreement between most data from the three sites gives confidence in the past and future use of the site A data as representing the water quality of the whole lake.

2. Methods

Detailed method descriptions are given in Appendix 1. The parameters measured routinely at 2-3 weekly intervals are:

- depth-related temperature and dissolved oxygen (DO), using the RBR XR420f CTD profiler. Additional parameters of conductivity and chlorophyll fluorescence recorded by the profiler sensors are available at NIWA and will only be reported as appropriate;
- water clarity by Secchi disc depth (20-cm black and white quartered);
- chlorophyll *a*, nitrate+nitrite-nitrogen ($\text{NO}_3\text{-N}$), ammoniacal-N ($\text{NH}_4\text{-N}$), dissolved organic N (DON), particulate-N (PN), dissolved reactive phosphorus (DRP), dissolved organic phosphorus (DOP), particulate phosphorus (PP), and algal species dominance in integrated-tube water samples from the top 10 m. Total nitrogen (TN) and total phosphorus (TP) are estimated by summation of particulate plus dissolved inorganic and organic N and P. Zooplankton net hauls from 100 m (63 μm mesh) are preserved in 4% formalin and stored pending analysis.

Water samples have also been collected at the same time from just above the lake bed (150 m) for analysis of $\text{NO}_3\text{-N}$, $\text{NH}_4\text{-N}$, and DRP to assess nutrient accumulation in the hypolimnion and to assess the extent of winter mixing.

For whole water column sampling, the parameters measured at 10 m depth intervals from the surface to the bottom of the lake twice a year are:

- conductivity, pH, temperature, DO, chlorophyll *a*, DRP, DOP, PP, TP, $\text{NO}_3\text{-N}$, $\text{NH}_4\text{-N}$, DON, PN, TN, urea nitrogen (Urea-N), total suspended solids (SS), volatile suspended solids (VSS), particulate carbon (PC), and dissolved organic carbon (DOC).

Additional parameters measured twice yearly, but not as complete profiles were:

- algal species composition and abundance on water samples from 1, 10, 50, 100 and 140 m.

Details of data handling and the treatment of values that are near analytical detection limits are described in Appendix 1.

2.1 Report contents

This report presents the results from the 2006/2007 stratified period plus the winter 2007 mixing, and refers to data in previous annual monitoring reports from 1995 to 2005 (Gibbs 1995, 1997a, 1997b, 1998, 2000a, 2000b, 2002, 2004, 2005, 2006, 2007; Gibbs et al. 2002) for inter-annual comparisons, and archived historical data since 1974 held by NIWA. The methods used are as per the 1994/95 report and a copy of these methods is included in Appendix 1. The calculation of the net VHOD rate, as applied to Lake Taupo data, was described in the 1996/97 report and a copy is presented in Appendix 2. Copies of temperature and dissolved oxygen, and nutrient data from the previous twelve years are included in Appendix 3 and 4 respectively. Graphical presentations of historical time-series temperature, dissolved oxygen, and Secchi disc depth data collected since the start of this monitoring programme are updated and presented in figures in the text. Phytoplankton species composition and dominance data for 2006/07 are included in Appendix 5 and discussed in the text. Graphical presentations of all available chlorophyll *a* concentration and Secchi depth water clarity data are presented where appropriate. Historical nitrate and dissolved reactive phosphorus data from spring and autumn full lake profiles are presented in Appendix 6 for reference.

2.2 Statistical evaluation

Simple statistical evaluation of data has been made using Microsoft Excel® and regression results have been reported to \pm 95% confidence limits. Statistical significance (P), where used, is qualified with the coefficient of determination (r^2) and the number of data points used (n). For details see Statistical Methods, Appendix 1.

Note that statistical significance is dependent on the number of data points used. Comparisons between trends should only be made where there are similar numbers of data points.

2.3 “TREND” definition

As in previous reports, the word “trend” is used in the context of a change between the start and the end of a time series data set where the use of a linear regression analysis

shows a statistically significant difference from the null hypothesis of there being no change. Use of the word “trend” is a statistical one. It does not imply any valid *extrapolation* of the observed change beyond the period of the data set being examined by the linear regression.

3. Results and discussion

3.1 Temperature and dissolved oxygen

Depth profiles of temperature and dissolved oxygen (DO) were measured at the mid lake site, Site A (Fig. 1), at about 2-3 weekly intervals, depending on the weather, throughout the year. These data, plus profiles measured during the full water quality samplings at Site A on 1 November 2006 (spring) and 3 April 2007 (autumn), are presented in Appendix 3. The time-series temperature and DO data from 20 m (epilimnion) and 130 m (hypolimnion) collected in the monitoring programme since 1994 are presented in Figure 2.

Temperature and DO data indicate that Lake Taupo was well mixed in winter 2006 with the mixing period being from mid-July to early September. Rapid cooling in bottom waters followed but not as strong as in winter 2004 (Fig. 2A). The lake was also well mixed in winter 2007. Surface water temperatures in summer 2006/07 had an extended period above 18 °C through to April.

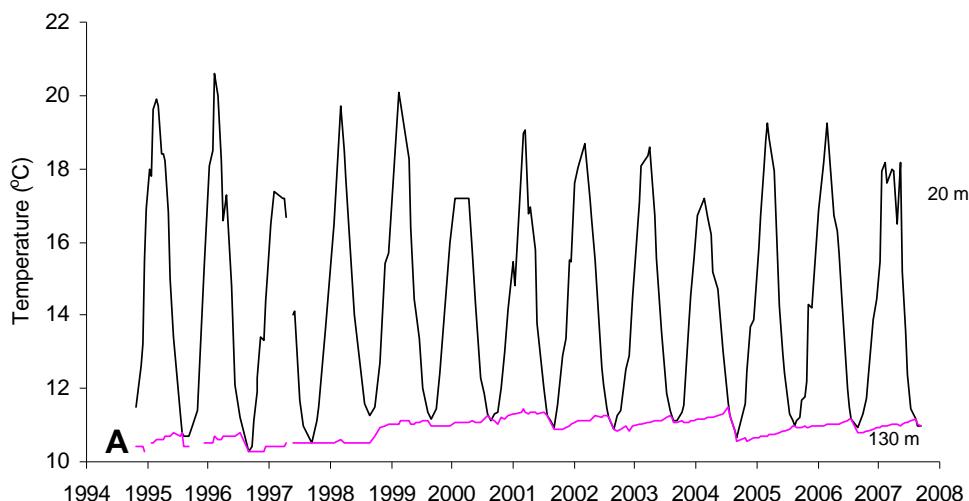

Figure 2A: Time-series temperature from 20 m (black line) and 130 m (pink line) depths. Winter mixing occurred where these two lines meet. The data show the lack of mixing in winter 1998 and only partial mixing in 1999. Mixing was brief in 1997 and 2005.

Despite years with incomplete mixing, the dissolved oxygen content of the hypolimnion has rarely fallen below 7.0 g m^{-3} , even close to the sediment. During winter mixing in 2006 and 2007 the bottom oxygen concentrations exceeded 10.0 g m^{-3} (Fig. 2B) confirming the high degree of mixing inferred from the temperatures (Fig. 2A).

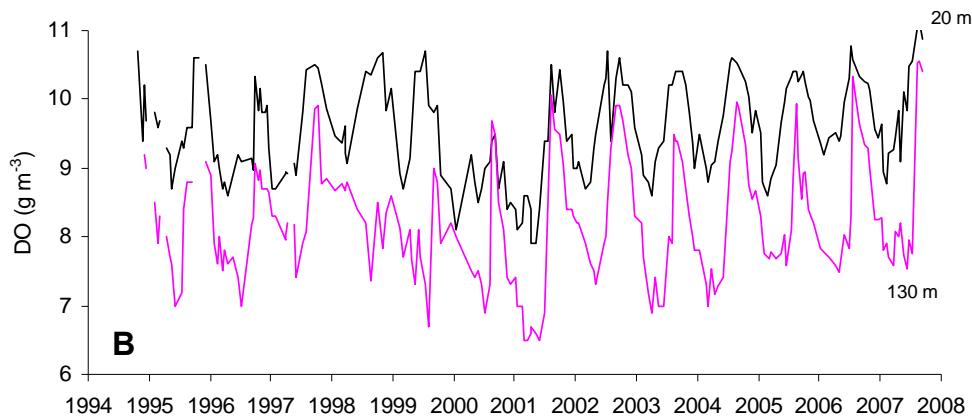

Figure 2B: Time-series dissolved oxygen data from 20 m (black line) and 130 m (pink line) depths. Mixing and complete reoxygenation occurred where the 2 lines in the temperature data (Fig. 2A) meet each winter. This corresponds with the period that the difference in oxygen concentrations between 20 m and 130 m is least. However, where temperature data indicate incomplete mixing there is reduced reoxygenation of the hypolimnion. Date ticks are 1 January in each year.

3.2 VHOD rate

The VHOD rate was estimated between September 2006 and March 2007 based on oxygen profile data collected at site A (Mid Lake). The VHOD rate in 2006/2007 was $10.73 \pm 2.45 \text{ mg m}^{-3} \text{ d}^{-1}$ (mean \pm 95% confidence limit) (Fig. 3). This value was about $1 \text{ mg m}^{-3} \text{ d}^{-1}$ higher than the value for 2005/06 at $9.56 \pm 2.24 \text{ mg m}^{-3} \text{ d}^{-1}$ (Table 1), but not significantly different.

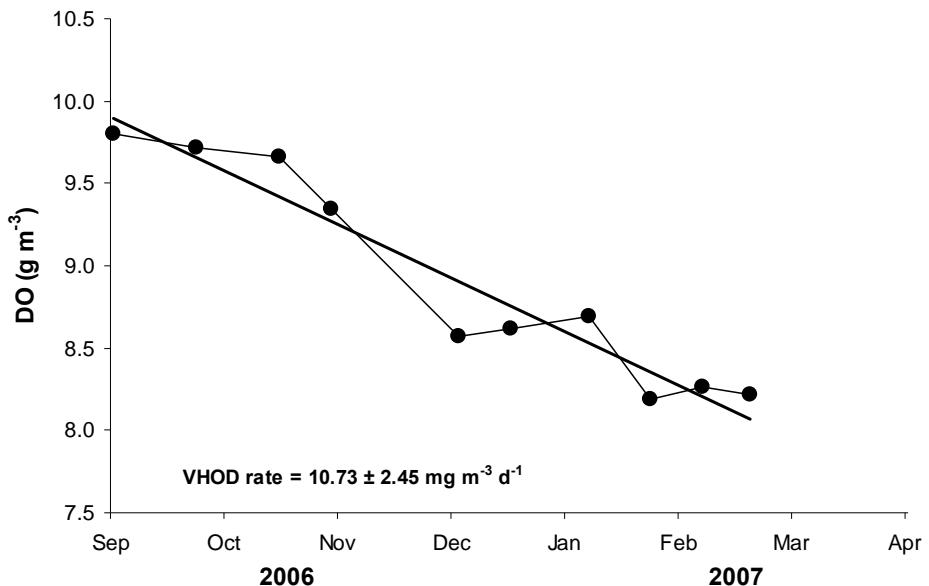

Figure 3: Time-series of volume-weighted mean dissolved oxygen concentration below 70 m depth in Lake Taupo for 2006/2007. VHOD is estimated from the linear regression through these data points. ($P < 0.001$, $r^2 = 0.93$, $n = 10$).

Table 1: Summary of VHOD rates ($\pm 95\%$ confidence limit) and the dominant phytoplankton species during the preceding winter bloom.

Year	VHOD rate	Dominant phytoplankton species	
1994-95	8.93 (2.39)	<i>Aulacoseira granulata</i> *	Diatom
1995-96	9.07 (2.77)	<i>A. granulata</i>	Diatom
1996-97	5.12 (1.37)	<i>Botryococcus braunii</i>	Colonial green
1997-98	3.21 (2.03)	<i>B. braunii</i>	Colonial green
1998-99	2.64 (1.90)	<i>B. braunii</i>	Colonial green
1999-00	5.11 (1.14)	<i>B. braunii</i> + <i>A. granulata</i> + <i>Cyclotella stelligera</i>	C.G. – Diatom mix
2000-01	9.34 (2.9)	<i>A. granulata</i>	Diatom
2001-02	9.06 (2.7)	<i>Asterionella formosa</i>	Diatom
2002-03	13.76 (2.14)	<i>A. formosa</i> + <i>A. granulata</i>	Diatom
2003-04	11.50 (2.80)	<i>A. formosa</i> + <i>A. granulata</i>	Diatom
2004-05	11.30 (1.13)	<i>Fragilaria crotonensis</i> + <i>A. formosa</i>	Diatom
2005-06	9.56 (2.24)	<i>A. formosa</i> + <i>A. granulata</i>	Diatom
2006-07	10.73 (2.45)	<i>A. granulata</i>	Diatom

* Not measured in winter but measured in October 1994.

3.3 Secchi depth

The time-series Secchi depth data (Fig. 4) show the annual cycle of water clarity is low in winter and high in summer, mostly within the range of 10 – 20 m and has a mean value of 15.7 m for the period shown. The annual cyclical pattern inversely follows the seasonal pattern of phytoplankton abundance, with low clarity during the winter/spring growth phase and high clarity during summer when the phytoplankton have sedimented out of the epilimnion, which is depleted in plant growth nutrients.

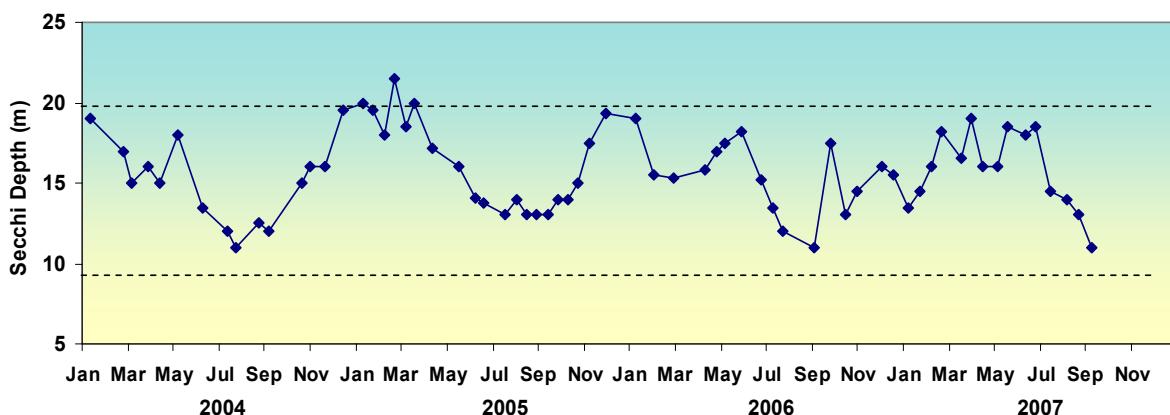

Figure 4: Water clarity as indicated by Secchi disk depth from summer 2004 through winter 2007. Broken lines represent 10 m and 20 m. Date ticks are 1st of each month.

Since 2003 the minimum winter water clarity (Secchi depth) values have been more than 12 m (Figs. 4, 5). There has also been a significant increase ($P < 0.0001$) in the annual mean water clarity over the monitoring programme since 1994, (Fig. 5). These observations are not consistent with the increase in maximum chlorophyll *a* concentrations in winter (See section 3.4, Fig. 7) and the significant increase in mean chlorophyll *a* concentrations (Fig. 6).

It is also apparent that, while water clarity in summer 2006/2007 was lower than the previous 2 years, the pattern of water clarity was comparable with summers over the previous 4 years when the period of high clarity has extended well into autumn (Figs. 4, 5). A continuation of this pattern is already apparent for 2007/08 with water clarity through spring and early summer (Fig. 5) showing exceptional clarity which reached a maximum value of 25 m. This is the highest clarity recorded for Lake Taupo. This extreme clear-water phase coincided with a drought (declared officially) and thus may reflect the reduced surface runoff and rainfall water input of nutrients as well as a low input of sediment.

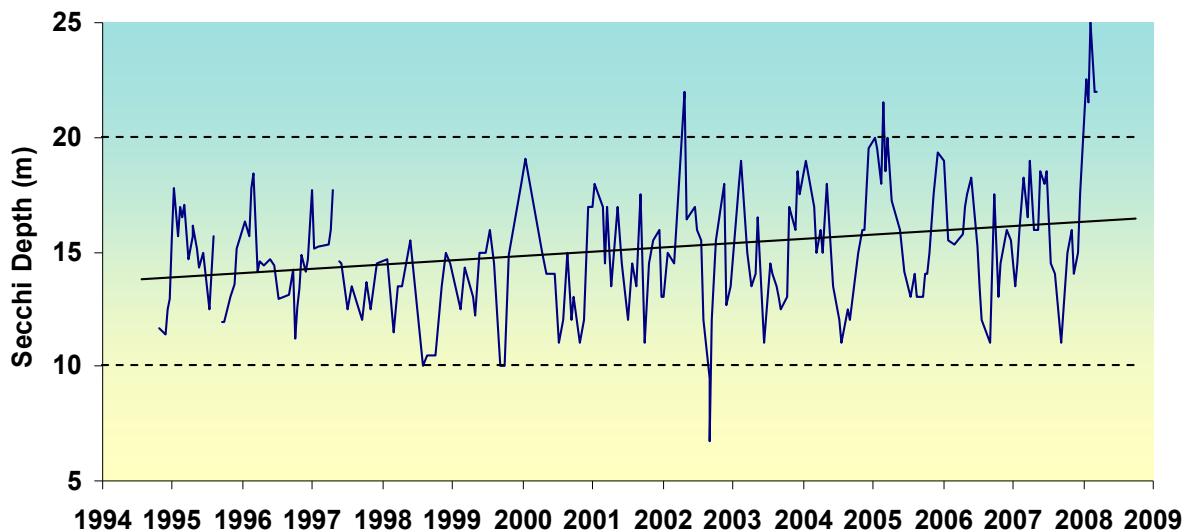

Figure 5: Long-term changes in water clarity as indicated by Secchi depth shows the variability across seasons and years for the present monitoring programme since 1994. The regression line shows a statistically significant increase in clarity of $0.19 \pm 0.08 \text{ m y}^{-1}$ ($P < 0.0001$, $r^2 = 0.083$, $n = 221$). The broken lines mark 10 m and 20 m. Date ticks are 1 January in each year.

3.4 Phytoplankton

The long-term trend of increasing chlorophyll *a* concentration in the upper 10 m of the water column at the mid lake site has continued, with higher than expected concentrations in both summer and winter 2007. The mean rate of increase [all data] was $0.038 \pm 0.019 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P < 0.0002$, $r^2 = 0.07$, $n = 210$) (Fig. 6).

The overall pattern of chlorophyll *a* concentration since 1994 is one of maximum concentrations during the winter algal bloom and minimum concentrations in early summer and there is a statistically significant ($P < 0.0001$, $r^2 = 0.18$, $n = 175$) inverse logarithmic relationship between chlorophyll *a* concentration and Secchi disk depth as discussed in the 2004/05 report (Gibbs 2006).

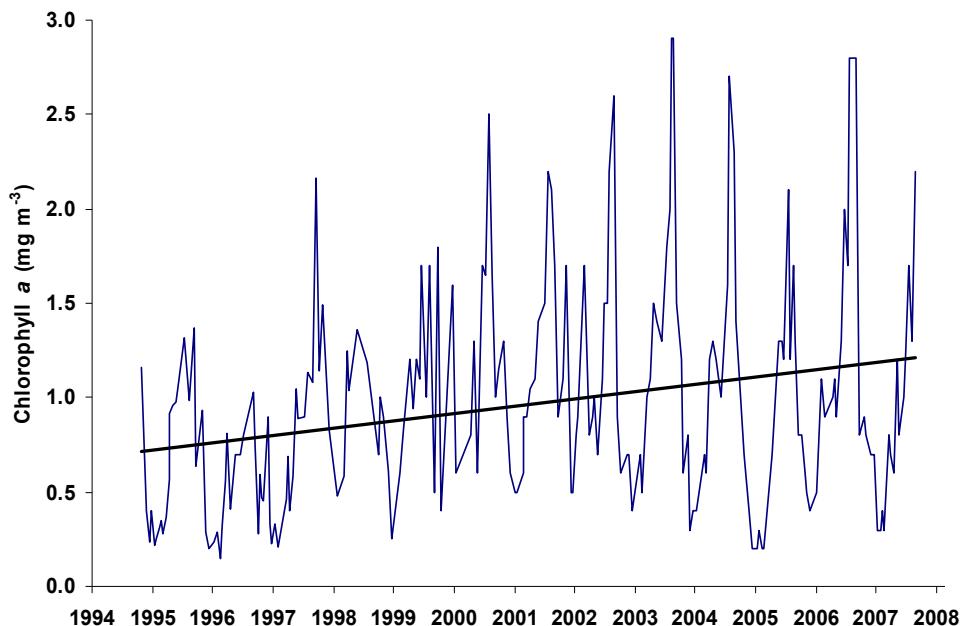

Figure 6: Time-series chlorophyll *a* concentrations in the upper 10 m of Lake Taupo at the mid-lake site, Site A. The solid regression line represents a statistically significant increase in the mean chlorophyll *a* concentrations of $0.038 \pm 0.019 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P < 0.0002$, $r^2 = 0.07$, $n = 210$). Date ticks are 1 January in each year.

In the previous report (Gibbs 2007), it was noted that the low chlorophyll *a* concentrations in winter and spring 2005 corresponded with the exceptionally high water clarity at that time and appeared to be the direct result of incomplete mixing in winter 2005. It was suggested that as a consequence of incomplete mixing, only part of the nutrient mass accumulated in the hypolimnion became available for phytoplankton growth in the winter-spring bloom of 2005. The remainder of that nutrient mass should have been carried over to the next stratified period, but was not seen in the dissolved nutrient pool in the hypolimnion (see section 3.7.1, Fig. 10).

There was an extended period of very high chlorophyll *a* concentrations in winter-spring 2006 (2.8 mg m^{-3}) following complete mixing in winter 2006. The maximum chlorophyll *a* concentrations in winter-spring 2007 were not as high (2.2 mg m^{-3}) (Figs 6 & 7).

Evaluation of the chlorophyll *a* data on a seasonal basis shows that the winter maximum concentrations have increased at $0.12 \pm 0.06 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P < 0.001$, $r^2 = 0.59$, $n = 14$) since 1994 while the annual mean concentrations have increased at $0.04 \pm 0.03 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P < 0.01$, $r^2 = 0.44$, $n = 14$) (Fig. 7).

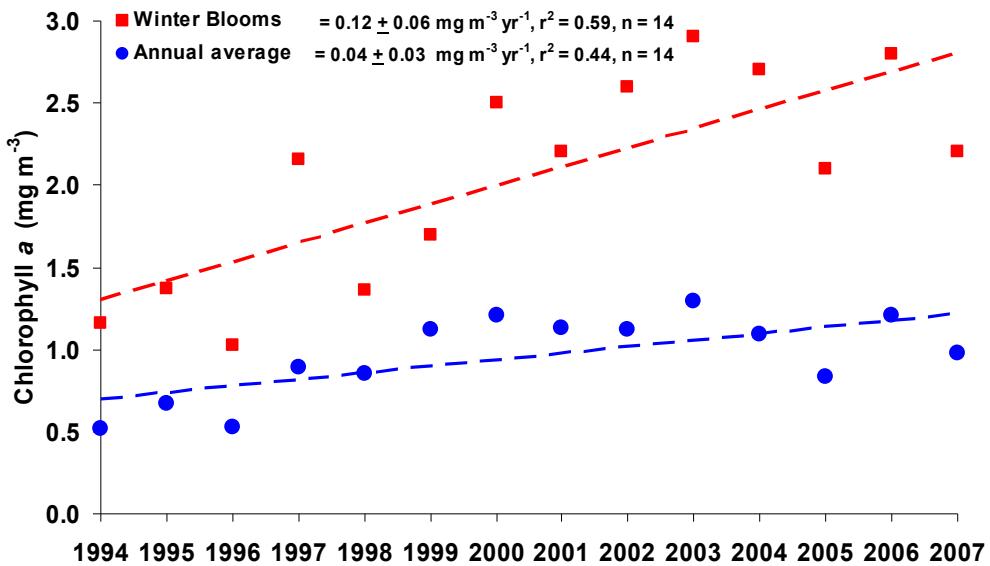

Figure 7: Annual average and winter maximum chlorophyll *a* concentrations from the 10-m tube samples since 1994. Regression lines indicate significant ($P<0.01$) trends in the data. Regression slopes are as given in the graph ($\pm 95\%$ confidence limit). Date ticks are monitoring years not calendar dates.

This increase in chlorophyll *a* concentration may not have been continuous. From 1994 to 1999, inclusive, the mean winter maximum chlorophyll *a* concentration was 1.46 mg m⁻³ and chlorophyll *a* concentrations were increasing at the rate of about 0.18 mg m⁻³ y⁻¹. From 2000 to 2007, the mean winter maximum chlorophyll *a* concentration was 2.5 mg m⁻³ and there was no statistically significant trend in the data. In contrast, from 2000 to 2007, the mean summer minimum chlorophyll *a* concentration was 0.52 mg m⁻³ and concentrations have decreased by about 0.09 mg m⁻³ y⁻¹.

The monitoring programme uses the chlorophyll *a* concentrations as an indicator of algal biomass in the upper 10 m. Chlorophyll *a* concentrations there can be directly related to water clarity as indicated by Secchi depth. However, the use of the profiler fitted with a chlorophyll fluorescence sensor has shown that a large proportion of the algal biomass in Lake Taupo through spring and summer is associated with the thermocline at 40 m depth as a deep chlorophyll maximum (DCM). Assuming a constant chlorophyll *a* to chlorophyll fluorescence ratio, the DCM has a potential biomass about 70% greater than that in the 0-to-10 m layer (Gibbs 2007). Further analysis of the fluorescence profile data may indicate whether there has been a change over time in the algal biomass associated with the DCM.

3.5 Species abundance

In the 2006-07 monitoring period, there were 3 major algal species which consistently reached a dominance³ level of 1 to 3 (1 = dominant, 10 = rare) at Site A. These were *Aulacoseira granulata*, which was the dominant species through winter and spring, *Dinobryon* in early summer and *Botryococcus braunii* through mid to late summer. Cyanobacteria were present on most occasions at low levels with *Anabaena lemmermannii* being the most abundant at a dominance value of 3 on one occasion in March 2007. Algae collected from the DCM in April 2006 were dominated by dinoflagellates (*Dinobryon* and *Gymnodinium* sp.), which are motile species that can move down from high to low light levels to take advantage of the flux of nutrients diffusing up from the hypolimnion when the epilimnion is nutrient depleted.

3.6 Nutrients in the upper waters

Time-series plots of DRP (Fig. 8A), NH₄-N (Fig. 8B), NO₃-N (Fig. 8C) and DON (Fig. 8D), showed values within the seasonal range measured over the whole period of the present monitoring programme since 1994. As previously noted (Gibbs 2006), nutrient concentrations changed abruptly at the time of the Mount Ruapehu eruptions in 1995 and slowly returned to pre-eruptions levels by 2003 (Fig. 8). Since 2003, fluctuations in the surface NO₃-N concentrations (Fig. 9) have mostly corresponded with winter mixed periods when nutrient enriched bottom waters (Fig. 10) were dispersed up through the lakes water column.

The low NO₃-N but high DRP concentrations associated with the incomplete mixing in winter 2005 are in contrast to the high NO₃-N but low DRP concentrations following the sudden and complete mixing in winter 2006. Following that mixing, dissolved inorganic nitrogen concentrations were extremely low due to algal uptake which produced very high biomass, as indicated by chlorophyll *a* concentrations (Fig. 6), in spring. Because there was still DRP present in the upper water column at that time, these data suggest that the phytoplankton ran out of nitrogen for growth, i.e., they became more⁴ nitrogen limited. This is in contrast with winter 2006 where high NO₃-N and low DRP concentrations coupled with high chlorophyll *a* concentrations (Fig. 6), suggest that the phytoplankton became less nitrogen limited.

³ Algal dominance is estimated from biovolume rather than cell counts.

⁴ Phytoplankton in Lake Taupo are nitrogen limited almost all the time.

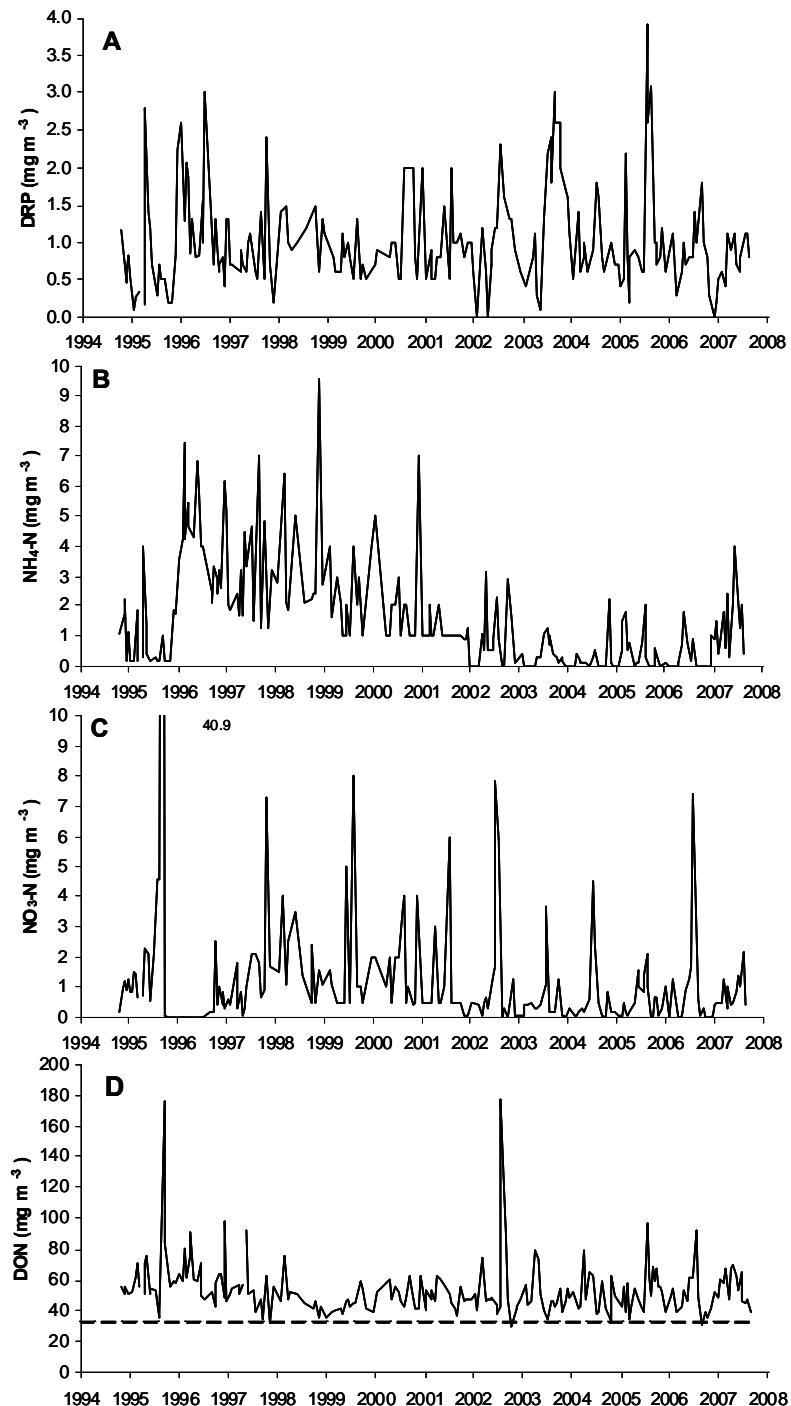

Figure 8: Time series data from the top 10 m of water column in Lake Taupo for (A) dissolved reactive phosphorus (DRP), (B) ammoniacal nitrogen ($\text{NH}_4\text{-N}$), (C) nitrate + nitrite nitrogen ($\text{NO}_3\text{-N}$), and (D) dissolved organic nitrogen (DON). Broken line indicates the minimum DON concentration, which may be the concentration of refractory organic material in the lake. Date ticks are 1 January in each year.

While the DON concentrations (Fig. 8D) do not show an obvious pattern, DON concentrations were lowest when the phytoplankton were most nitrogen limited i.e., in summer.

A feature of the 2006/2007 nutrient data were the higher, relative to 2002-2006, NH₄-N concentrations in the upper water column from January through to August 2007 (Fig. 9). While NH₄-N blips are often seen in the surface water at the time of winter mixing and have been attributed to upwelling of nutrient-rich bottom water, the timing and duration of this NH₄-N blip cannot be linked to an upwelling event. Consequently, it is possibly related to water column decomposition of senescent phytoplankton. This conclusion is consistent with the 0-to-10m NH₄-N concentrations being higher than those in the hypolimnion (Fig. 10).

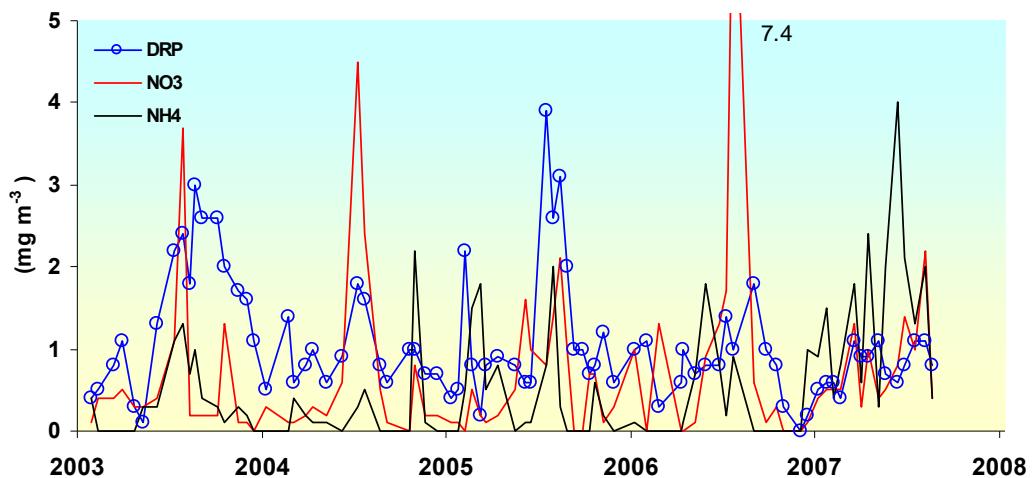

Figure 9: Time series data from the top 10 m of water column in Lake Taupo for dissolved reactive phosphorus (DRP), nitrate + nitrite nitrogen (NO₃-N) and ammoniacal nitrogen (NH₄-N) since January 2003. The elevated NH₄-N concentrations in autumn 2007 may be due to water column decomposition of organic matter. Date ticks are 1 January in each year.

3.7 Nutrient accumulation in the hypolimnion

3.7.1 Total mass accumulated

Dissolved inorganic nutrients in water samples from 150 m demonstrated consistent seasonal patterns which can be used to define the time of complete mixing in winter (Fig. 10). Winter mixing was indicated by the sudden drop in DRP and NO₃-N concentrations that usually occurs around the beginning of August. It is clear (Fig. 10) that NO₃-N concentrations in the hypolimnion before winter mixing have been

remarkably consistent at around 32-35 mg m⁻³ in the last 4 years. Also, with the exception of 2005, winter mixing has occurred in July each year (Fig. 10).

In 2005 mixing was incomplete and, in the following stratified period, deep NO₃-N concentrations were high from the start of stratification because of carry-over from the previous stratification period. However, the rapid increase in NO₃-N concentrations observed through the beginning of the stratified period in other years did not eventuate in spring 2005. This suggests that the smaller winter bloom in winter 2005 produced less algal decomposition in the hypolimnion as the bloom sedimented out of the upper water column in spring 2005. The time-series of NO₃-N concentrations through spring 2006 followed the expected pattern from years with complete mixing.

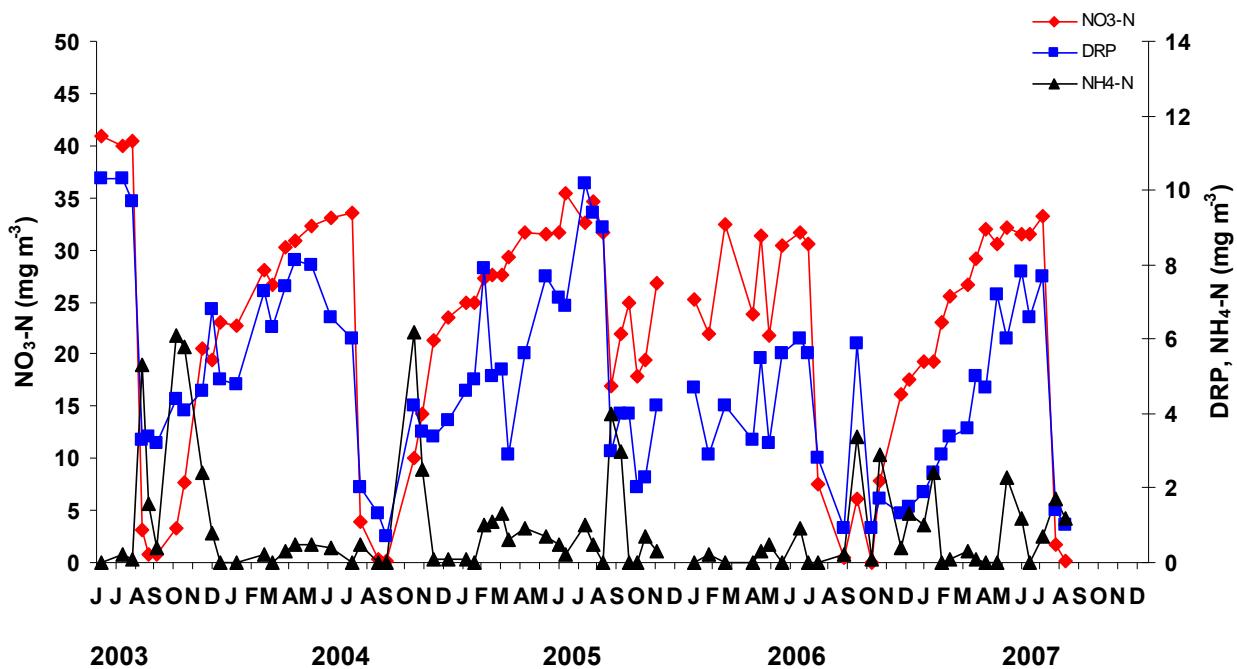

Figure 10: Time series data for DRP (blue square), NO₃-N (red diamond) and NH₄-N (black triangle) in the bottom waters of Lake Taupo since winter mixing 2003. Note the DRP and NH₄-N Y-axis scale (right side) is expanded for clarity.

The total mass⁵ of NO₃-N in the hypolimnion in autumn each year before winter mixing has ranged from about 120 t (1978) to more than 650 t (2000) (Fig. 11). While this graph is similar to those in earlier reports, this graph also includes all additional information from historical data sets held by NIWA. A copy of the historical source data used to produce the additional data points from 1975 to 1990 are included in

⁵ In previous reports the total mass of NO₃-N in the hypolimnion each year has been referred to as the “total accumulated mass” of NO₃-N. It is the “standing stock” of NO₃-N at that time.

Appendix 6. Including the additional historical data, since 1975 there has been a statistically significant ($P < 0.002$, $r^2 = 0.41$, $n = 20$) trend of increase in the total mass of $\text{NO}_3\text{-N}$ in the hypolimnion before winter mixing of around 8.4 t y^{-1} (Fig. 11).

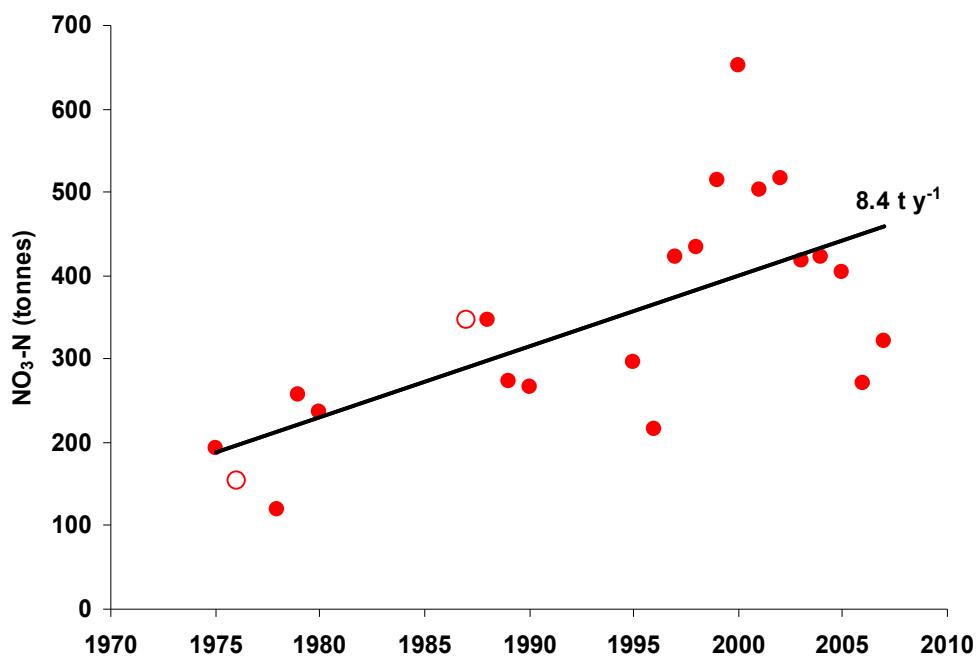

Figure 11: Long-term time series of total mass of $\text{NO}_3\text{-N}$ in the hypolimnion of Lake Taupo in autumn (~April) before winter mixing. The regression line indicates a statistically significant trend of increase in the total mass of 8.4 t y^{-1} ($P < 0.002$, $r^2 = 0.41$, $n = 20$). Open circle data excluded from regression as time periods and depth data were not the same as used for the other data. Date ticks are 1 January in each year.

3.7.2 Net accumulation rate

While the total mass of $\text{NO}_3\text{-N}$ in the hypolimnion is a “standing stock” before winter mixing, it is recognised that the standing stock is a function of the mass of $\text{NO}_3\text{-N}$ in the hypolimnion at the beginning of the stratified period plus the net mass that was released from the sediments plus algae decomposing in the water column and accumulated in the hypolimnion during the stratified period. While the standing stock is the mass present at one time, the mass released from the sediments over the stratified period can be expressed as a rate which may give a more reliable estimate of change.

To determine the net accumulation rate of $\text{NO}_3\text{-N}$ in the hypolimnion, the total mass data (Fig. 11) have been transformed into accumulation rate data by subtracting the

spring profile data from the autumn profile data and dividing by the number of days between the spring and autumn samplings (Fig. 12).

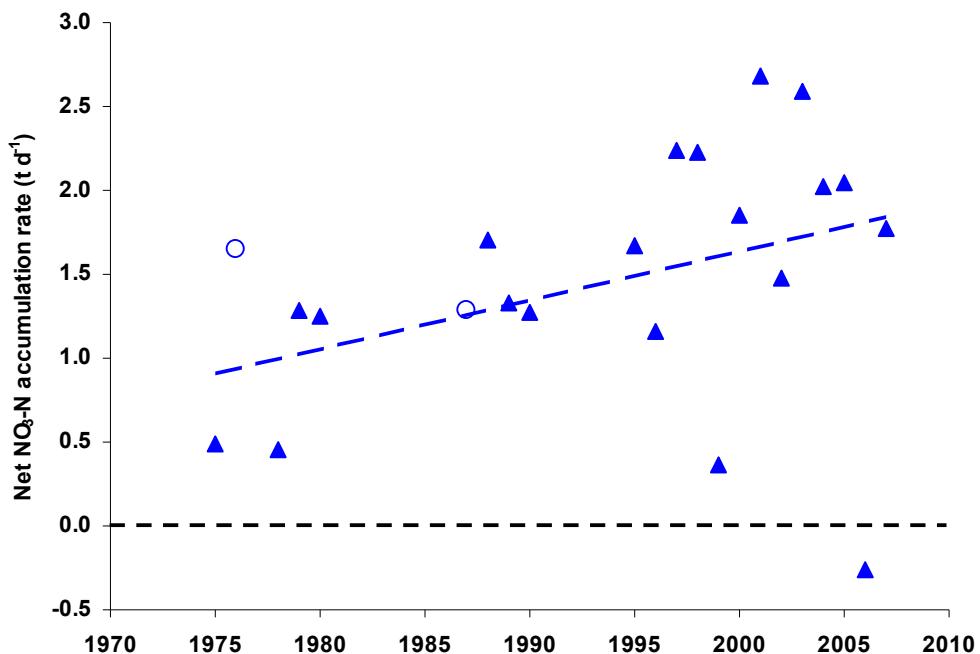

Figure 12: Net NO₃-N accumulation rates (t d⁻¹) in the hypolimnion below 70 m. The regression line shows an increase in the net accumulation rate of 0.03 t d⁻¹ ($P < 0.1$, $r^2 = 0.145$, $n = 20$). Open circle data were not included in the regression analysis (see text). Note that the Y-axis extends to -0.5 t d⁻¹ for the 2006 data point. Date ticks are 1 January in each year.

As sediment process rates are generally slow to change, the expectation would be for a reasonably consistent pattern to the net accumulation rates between years allowing any trends to be well defined. A regression through all of these rate data (Fig. 12) shows a weakly significant trend in the data with the net accumulation rate increasing at 0.03 t d⁻¹ each year ($P < 0.1$, $r^2 = 0.145$, $n = 20$) over the 32 year data record. The data for 1976 and 1987 (open circles, Fig 12) were excluded from the regression analysis because they are for different periods than the rest of the data (see also Fig. 11)).

The net accumulation rates of NO₃-N (Fig. 12) show a higher degree of variability between years than would be normally expected, with both the 1999 and 2006 data points (years following incomplete mixing) falling well below the spread of the rest of the data and the trend line. The negative net accumulation rate in 2006 indicates a substantial loss of NO₃-N from the hypolimnion during the 2005-06 stratified period.

Clearly this is not possible if the $\text{NO}_3\text{-N}$ accumulation was derived from sediment release only. The net loss is therefore an indication that net $\text{NO}_3\text{-N}$ accumulation in the hypolimnion also includes water column processes such as uptake by algae in the DCM at the top of the hypolimnion and the water column decomposition of algae falling from above. This suggests that the low or negative net $\text{NO}_3\text{-N}$ accumulation rates for years following a winter where there was incomplete mixing, are anomalies relative to the rest of the data. The effect of incomplete mixing was discussed in the previous report (Gibbs 2007). Note that the net accumulation rate for the 2006/2007 period, which had complete mixing, falls very close to the trend line (Fig. 12).

3.7.3 Total N

Total nitrogen (TN) mass in Lake Taupo was estimated from the spring profile in each year. Regression analysis found that, although there was an average increase of about 10 t y^{-1} over the data record, there was no statistically significant trend in the long-term time-series data for TN (Fig. 13). Coincidentally, the average increase of about 10 t TN y^{-1} is essentially the same as the average increase in the mass of $\text{NO}_3\text{-N}$ in the hypolimnion in autumn. Although these data are not directly linked, the algal bloom that develops following winter mixing contributes to the TN mass in the lake in spring.

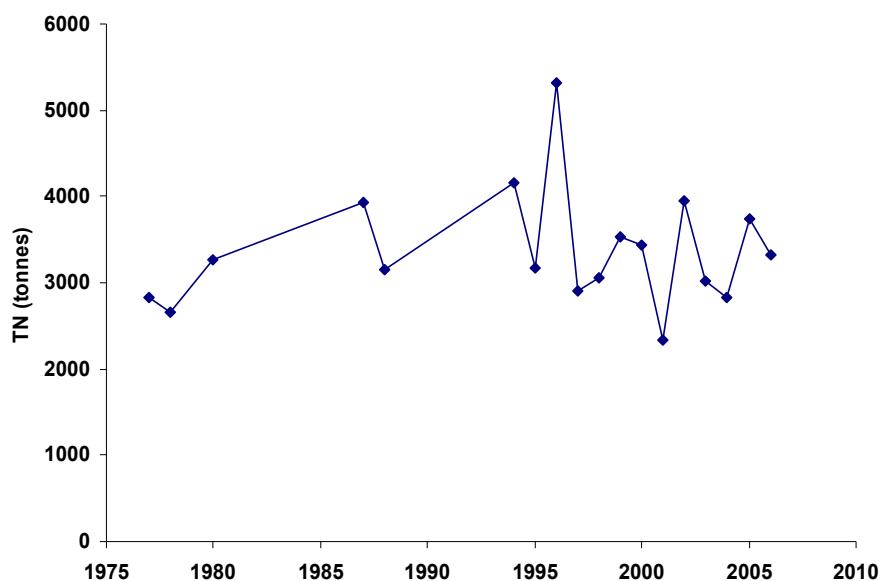

Figure 13: Long-term time series estimates of the mass of total nitrogen (TN) in Lake Taupo in spring after winter mixing. Although there is an average increase of about 10 t y^{-1} over the data record, this apparent trend in the data is not statistically significant. The mean of the mass is around 3370 t. Date ticks are 1 January in each year.

Although there is obvious interannual variability in the mass of TN in spring following winter mixing, the total mass of TN in Lake Taupo remains at around 3300 t despite a net annual external TN load on the lake of around 1200 t. This implies that around 1200 t of N are lost from the lake water column each year through sedimentation. This N may be buried or removed from the lake by denitrification.

4. Knowledge gaps

An earlier report (Gibbs 2006) commented on several knowledge gaps including in-lake processes in Lake Taupo, and process rates at the sediment-water interface. This report presents estimates of the net rate of NO₃-N accumulation in the hypolimnion during the stratified period. The low NO₃-N accumulation rate in the 2005/2006 stratified period following incomplete mixing in winter 2005, and the immediate return of the net accumulation rate to the trend in the net rate data the following year, points to water column processes being as important as sediment processes and highlights the need to understand how the in-lake processes work.

Despite a net input of TN to the lake of 1200 t y⁻¹ there is no apparent increase in the TN in the lake (Fig. 13). In addition, the total mass of NO₃-N in the hypolimnion just before winter mixing each year appears to reach a plateau (see shape of NO₃-N concentration curves Fig. 10). Together these data suggest that processes at the sediment-water interface and elsewhere in the hypolimnion are capable of sequestering very large amounts of N each year. However, as the net accumulation rate of NO₃-N in the hypolimnion is increasing, this suggests that the sediment processes of burial, decomposition, mineralisation, nitrification, and denitrification are changing.

We have little or no information on any of these process rates.

This report has also shown that both the mean annual water clarity and the mean annual chlorophyll *a* concentrations in the upper 10 m of water column have increased significantly since 1994. These parameters are usually inversely related and thus other factors must be influencing the observed increases. Note, the deep chlorophyll maximum, which may account for more than 70% of the algal biomass in Lake Taupo, is not being assessed.

5. Summary

- The annual mean chlorophyll *a* concentration in the upper 10 m of water column in Lake Taupo, as an indicator of phytoplankton biomass, has increased at a rate of $0.04 \pm 0.03 \text{ mg m}^{-3} \text{ y}^{-1}$ ($P < 0.01$, $r^2 = 0.44$, $n = 14$) over the 13 year monitoring period.
- Winter chlorophyll *a* maximum concentrations have increased at $0.12 \pm 0.06 \text{ mg m}^{-3} \text{ y}^{-1}$ ($r^2 = 0.59$, $n = 14$) since 1994 and the peak chlorophyll *a* concentration in winter 2006 at 2.8 mg m^{-3} was one of the highest on record.
- The trend of increase in the winter chlorophyll *a* maximum concentrations may not be linear and concentrations may have reached a plateau. Before 2000, mean winter chlorophyll *a* maximum concentrations were 1.46 mg m^{-3} with an increasing trend of $0.18 \text{ mg m}^{-3} \text{ y}^{-1}$. After 2000, mean winter chlorophyll *a* maximum concentrations were 2.5 mg m^{-3} with no statistically significant trend or apparent change in the data.
- There is a substantial deep chlorophyll maxima (DCM) below the thermocline (40 m) in the lake during spring and summer with an estimated chlorophyll *a* concentration about 70% higher than the chlorophyll *a* concentrations measured in the surface waters.
- Algal species dominance followed a succession from diatoms *Aulacoseira granulata* in winter and spring, with *Dinobryon* and *Botryococcus* becoming dominant in summer and autumn. Blue-green algae were always present in low numbers throughout 2006/2007 monitoring period, with *Anabaena lemmermannii* reaching a dominance level of 3 on one occasion in March 2007.
- Algae collected from the DCM in April 2006 were dominated by dinoflagellates (*Dinobryon* and *Gymnodinium* sp.), which are motile species that can move down from high to low light levels to take advantage of the diffusive flux of nutrients from the hypolimnion when the epilimnion is nutrient depleted.
- There was a statistically significant trend of increase in the total mass of $\text{NO}_3\text{-N}$ in the hypolimnion before winter mixing of around 8.4 t yr^{-1} ($P < 0.002$, $r^2 = 0.41$, $n = 20$). This increase is comparable with the non-statistically significant increase in whole Lake TN of about 10 t y^{-1} . While not directly linked, following winter

mixing the accumulated $\text{NO}_3\text{-N}$ in the hypolimnion in autumn stimulates algal growth which contributes to the TN measured in spring.

- The net accumulation rate of $\text{NO}_3\text{-N}$ rate in the hypolimnion below 70 m in the last few years has been in the order of 2 t d^{-1} and regression analysis showed that there has been a weakly significant trend of increase in that rate of 0.03 t d^{-1} each year ($P < 0.1$, $r^2 = 0.145$, $n = 20$) over the last 32 years.
- The net accumulation rate of $\text{NO}_3\text{-N}$ in the hypolimnion in 1999 and 2006 were much lower than the trend and the data indicate that there was a net loss of $\text{NO}_3\text{-N}$ from the hypolimnion in 2006. As sediment release should have been positive and is unlikely to change rapidly, these apparent anomalies point to water column processes in the hypolimnion being of similar importance to sediment processes.
- The 2006/2007 net VHOD rate for the period from September 2006 to March 2007 was $10.73 \pm 2.45 \text{ mg m}^{-3} \text{ d}^{-1}$ (mean \pm 95% confidence limit) which was less than the previous year at $9.56 \pm 2.24 \text{ mg m}^{-3} \text{ d}^{-1}$.
- Nutrient concentrations (DRP, $\text{NH}_4\text{-N}$, and $\text{NO}_3\text{-N}$) in the upper water column were generally comparable with concentrations since 2003 and are similar to historical concentrations before Mount Ruapehu erupted in 1995.
- There were indications that N-limitation developed during spring 2006 following winter mixing in 2006 when substantial amounts of $\text{NO}_3\text{-N}$ were dispersed through the upper water column, driving the record high phytoplankton biomass (reported above).
- Bottom water temperatures rose to just above 11°C through the 2006/2007 period.
- Water clarity during summer 2007 was higher on average than in most previous summers, and the high clarity period extended into late autumn.
- Extremely high water clarity (Secchi depth 25 m) in summer 2008 may be attributed to the extended period of calm weather and very low surface run-off during the drought contributing less plant growth nutrients and sediment to the lake than in previous years.

In a previous annual report (Gibbs et al. 2002), 3 trends in the data were identified — increasing phytoplankton biomass in the upper 10 m, increasing $\text{NO}_3\text{-N}$ mass in the

lake hypolimnion prior to winter mixing, and an increasing range in the variability of water clarity — that were of concern with respect to the water quality of Lake Taupo. In the previous report, it was also shown that the net accumulation rate of NO₃-N in the hypolimnion during the stratified period has increased over the last 30 years, although the trend was not strong.

These trends in the data are still present.

6. Acknowledgments

This report was made possible by the team effort of Les Porter and Brent McIntosh of the Taupo Harbourmaster's Office, and Eddie Bowman (NIWA Rotorua) who have collected the data. Much of the success of this monitoring programme is attributable to the extra effort by Eddie and the team.

Water samples were processed in the NIWA chemistry laboratory and analytical results were provided by Graham Bryers, Denise Rendle, Stu Pickmere and team. Quality control was provided by Mike Crump, Lab Manager.

Phytoplankton dominance and enumeration results were provided by Karl Safi.

8. Appendix 1. Site map, sampling strategy and methods

Lake monitoring sites were originally established using land-based markers (Fig.1). These have now been defined using GPS and corrected for curvature using WGS84 convention.

Site Map

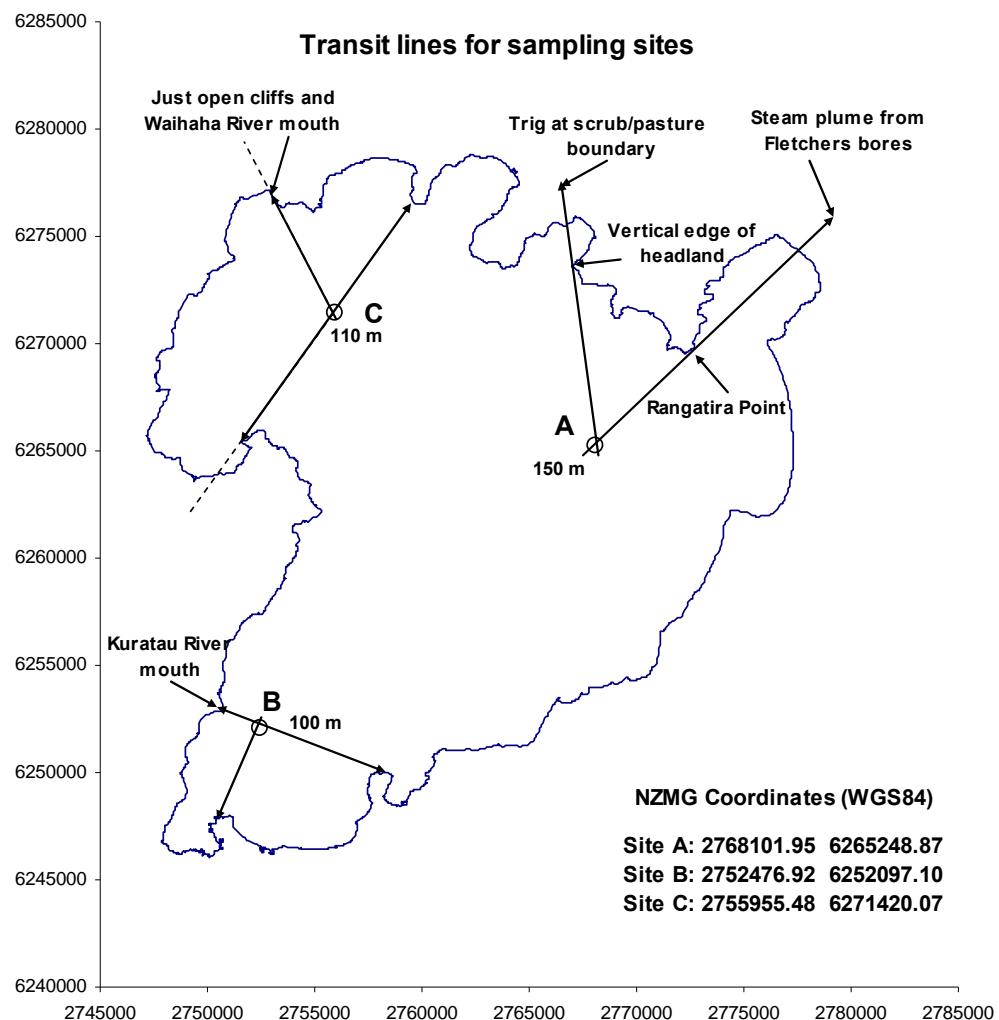

Figure 1: Site map of Lake Taupo showing location of the routine monitoring site at mid-lake (A). Two additional sites at Kuratau Basin (B) and the Western Bays (C) were sampled between January 2002 and December 2004 inclusive. Data from those sites have been retained with the Site A data presented in the appendices. Map coordinates are in NZ Map Grid with WGS84 correction. Lat. Long WGS 84 corrected co-ordinates of "Site A" are 38° 46'.810 S; 175° 58'.440 E.

The following section has been copied from Gibbs 1995, and modified after 1998.

8.1 Methods

The sampling site was selected in the central basin of Lake Taupo (Site Map) with a water depth of about 150 m. This site is more than 5 km from the nearest land and is exposed to both the north-south and east-west axis of the lake.

To calculate VHOD requires two measurements each year far enough apart in time for a measurable change to occur in the DO concentrations in the hypolimnion of the lake. Details of the procedure and limitations of this measurement are described by Vant (1987). For the monitoring of Lake Taupo, which mixes briefly in winter between July and August, the initial sampling time was selected to be in October, to give sufficient time for thermal stratification to establish a stable hypolimnion. The final sampling time was selected to be in April, before lake cooling causes the downward movement of the thermocline which precedes the winter mixing.

At each of these biannual samplings, a detailed profile of DO and temperature was measured. Prior to 1998, measurements were made at 1 m depth intervals through the full depth of the water column using an *in situ* recording Applied Microsystems STD-12 profiler fitted with a Royce DO sensor, and compared with manual measurements of DO and temperature made at 10 m depth intervals from the surface to the bottom of the lake using a Yellow Springs Instrument (YSI) model 58 dissolved oxygen meter fitted with a stirred Model 5739 probe on a 160 m cable. Subsequent to 1998, a Richard Brancker Research (RBR) model TD410 conductivity-temperature-depth (CTD) profiler fitted with a stirred YSI model 5739 DO sensor was used. In January 2002, the TD410 CTD profiler was upgraded to an RBR model XR420f freshwater CTD profiler fitted with the YSI model 5739 DO sensor and a Seapoint chlorophyll fluorescence probe. The DO sensor was calibrated regularly by NIWA, Rotorua staff and chlorophyll fluorescence was converted to chlorophyll *a* from extracted chlorophyll *a* analyses of water samples collected beside profiler.

The following parameters were also measured as profiles from water samples collected using a van Dorn water sampling bottle starting at 1 m and then at 10 m intervals from 10 m to the bottom of the lake:

DO, chlorophyll *a*, dissolved reactive phosphorus (DRP), dissolved organic phosphorus (DOP), particulate phosphorus (PP), total phosphorus (TP), nitrate + nitrite nitrogen* ($\text{NO}_3\text{-N}$), ammoniacal nitrogen ($\text{NH}_4\text{-N}$), dissolved organic nitrogen

(DON), particulate nitrogen (PN), total nitrogen (TN), urea nitrogen (Urea-N), total suspended solids (SS), volatile suspended solids (VSS), particulate carbon (PC), dissolved organic carbon (DOC), and water colour. (* Little, if any nitrite is ever found in the Lake Taupo water column, hence the use of NO₃-N, (unpub. Data)).

Note: TN and TP values are the summation of all other N and P components, respectively, excluding Urea-N which is part of the DON component.

Additional parameters measured were:

Water clarity (by Secchi disc depth) and algal species composition and abundance on water samples from 1, 10, 50, 100, and 140 m.

Determinations on the water samples were made with the standard methods routinely used for freshwater analysis by NIWA.

Data for the long term monitoring programme were scheduled to be collected from the mid-lake sampling station at 2 weekly intervals. The practicality of achieving this target was limited by the weather and in reality data were generally collected at about 2-3 weekly intervals. Parameters measured were:

DO and temperature profiles at 1 m depth intervals to the bottom of the lake by RBR XR420f profiler, water clarity as Secchi disc depth, and a 10 m tube water sample was collected for measurement of chlorophyll *a*, NO₃-N, NH₄-N, TN, DRP, TP, and algal species dominance.

Near-bottom water samples from 150 m were collected using a van Dorn water sampling bottle and analysed for DRP, NO₃-N, and NH₄-N.

8.2 Data handling and less than detection limit values

All data in this report have been processed and manipulated on Excel spreadsheets. Data is rounded using the Excel protocol to an appropriate number of significant numbers based on the need for detailed knowledge tempered with the confidence in the precision and accuracy of the analytical methods used. This treatment may lead to small differences between electronic copies of the data and the values presented in this report.

The difference between the written report and the Excel spreadsheet of essentially the same data is the treatment of the less than detection limit (<DL) results. The data have in the past been written as <DL or <DL(value). For statistical analysis the excel spreadsheet replaces <DL with 0 or uses the value in brackets in place of 0. Although it is recognised that the former action will be in error, the use of the value in brackets requires some justification.

In discussion with Burns Macaskill, Graham McBride, and Mike Crump from NIWA on this issue, the following conclusions were reached:

- In general the data is reported as a series of results from analytical methods which have known limitations and precision. The raw number is reported where ever possible so that the user can draw their own conclusions about the reliability of the "last significant figure" on any result when performing data manipulations.
- The real problem arises at very low levels and the result obtained is less than the method's prescribed DL. The problem is not so much the result obtained but what to do with it which in turn raises the question 'What do we mean by detection limit'?
- In the book "Statistical methods in water resources" Helsel & Hirsch 1992 [Studies in Environmental Science 49, Elsevier], and chapter 13 "Methods for data below the reporting limit" it is pointed out that the 'detection limit' is variously known as the 'reporting limit' or the 'limit of quantitation'. If no other value is available, there are 3 main options: call it zero (which is clearly an under estimate), call it the detection limit (which is clearly an over estimate), or call it half the detection limit (which gives a 50:50 chance of an over or under estimate). The choice then is one of 'which convention do you wish to use'. In the written reports, I have treated the <DL as zero for summation purposes. This is an under estimate which I should have noted on each report page so that anyone using that data is aware of the convention used.
- An alternative approach is to say that, before the sample is analysed, the DL is the ***predicted minimum*** level that will be found using the stipulated method. However, once the sample is analysed the result is what was ***actually measured*** and may be <DL on the day of analysis. As it is an actual analytical result, that value (reported in brackets) should be reported even though it is <DL. This implies that the method DL is in reality a reporting level or level of confidence.

- The "DL" was derived for the Lake Taupo data, on each analytical occasion, from a series of blanks and 1ppb standards run with the samples. The "DL" is set as 3 times the SD of the 1 ppb standard. This is actually a limit of confidence. All samples are run in duplicate and the mean of the two results becomes the concentration reported.
- With the introduction of the Lachet flow injection analysis (FIA) system, the limits of detection have been confidently pushed to the point where replicate results may often be <DL. In these instances, in the written report, the value is reported as <DL(result). In the past I have still used the <DL = 0 convention in summation for the TN and TP data. This is obviously wrong and the actual result should be used, as is done in the electronic spreadsheet.

In this report the analytical value 'on-the-day' has been used wherever possible. Data reported as <DL use the <DL = DL/2 convention. Past data have not been corrected or altered to conform to this protocol.

These technical details are incorporated in this annual report so that data users are aware of how the 'DL' or confidence limit was set and how the values <DL are treated when performing data manipulations.

There is still the question of how to deal with numbers where the result has been simply reported as <DL. The use of the DL/2 convention is probably closer to reality than the DL = 0 convention.

Helsel & Hirsch suggest an alternative method for estimating a value in the <DL range. If there is sufficient real data >DL, a probability curve can be derived and extrapolated around the DL to generate the most probable number for the <DL value.

8.3 Statistical methods

Copied from Gibbs (2000b).

In this report we have used linear regressions and associated statistical tests to examine trends. The key result of these procedures is the coefficient of determination (r^2), which presents the amount of variability in the data that is accounted for by the

regression. Another is the P -value.⁶ This can be used as a weight of evidence against the hypothesis that there was in fact no trend. This weight is strong when P is small, meaning that a trend at least as large as that measured could have occurred merely by chance—we have only a limited number of data from which to infer the strength of any trend, so our measurements always are uncertain to some degree. So if P is low enough (taken as less than 5% in this report, which is the usual practice), it is conventional to say that the measured trend is "statistically significant", and that convention is followed in this report. However, it is important (and often not realised) to note that the P -value cannot be used as an *absolute* weight of evidence. This is because it tends to decrease as the number of samples taken in a given period is increased. For example, when we plot monthly Secchi disc depth data from 1994–2001 (Figure 3A, Gibbs 2000b) with these 93 data we obtain a statistically significant result (because $P < 0.05$)—even though the coefficient of determination was only $r^2 = 0.0445$. When we plot the minimum winter clarity over this period we then have only 7 data. In this case (Fig. 3B, Gibbs 2000b) we happen to have the same measured trend slope with a much higher coefficient of determination ($r^2 = 0.464$), yet the result is *not* statistically significant (because $P = 0.09$). This is entirely because of the reduced number of samples in the winter minimum case. What this makes clear is that the P value is useful as a *relative* weight of evidence when comparing datasets of the *same size*, but it has no evidential meaning when comparing results from datasets of very different sizes.

⁶ It is defined as the probability of obtaining a trend at least as extreme as was obtained if in fact there was no trend at all.

9. Appendix 2. The calculation of net VHOD rates

Copied from Gibbs 1995.

Rationale

In the strictest terms, VHOD can only be calculated for a lake which has thermally stratified and the resultant thermocline provides an effective barrier against re-oxygenation of the hypolimnion. The measure of the barrier efficiency is the rate of heating of the hypolimnion following stratification as heat will be transferred across the thermocline at a similar rate to oxygen.

In Lake Taupo, the thermal inertia of the hypolimnion is so great that heating during the stratified period is typically about 0.2 °C and never more than 0.4 °C over a 200 day period. While this would seem to meet the temperature criterion, in a lake that large, oxygen can be transferred into the hypolimnion by mechanisms other than diffusion.

Wind induced mixing may increase turbulent diffusion across the thermocline as would an internal seiche on the thermocline. Both of these mechanisms would transfer heat. The penetration of the thermocline by an underflowing density current would entrain oxygenated surface water into the hypolimnion with that flow. As the density current must be colder than the thermocline to plunge through it, there is no heat transferred with this mechanism.

In Lake Taupo the Tongariro River is always colder than the surface water and for at least 9 months of the year it is also colder than the minimum lake water temperature of 10.3 °C. Thus, during most of the stratified period, the Tongariro River flows directly into the hypolimnion entraining oxygenated surface water with it. The amount of surface water entrained has been estimated to be about 10 times the river discharge. The amount of oxygen transported in this way is likely to be more than 200 tonnes per day (Gibbs 1996).

Clearly this is a substantial oxygen input which invalidates the concept of the thermocline forming an oxygen barrier for purposes of calculating the VHOD. The true VHOD may only be calculated during mid summer when the Tongariro River flows deep into the epilimnion but does not penetrate the thermocline.

The data collected to date indicates that hypolimnetic oxygen depletion occurs throughout the stratified period - with or without the density current re-oxygenation - and hence the value obtained from a VHOD calculation over the whole stratified period is the net VHOD rate taking all the factors affecting the hypolimnion into account.

As the data from 1996/97 shows, the density current also advects dissolved organic nutrients with it. Hence, management strategies which affect the Tongariro River also impact on the lake. Hence it is appropriate to use the net VHOD rate for interannual comparisons rather than the true VHOD rate calculated only through mid summer.

Method of calculation

The following is the method used to calculate the net VHOD rate for Lake Taupo.

Requirements: Microsoft EXCEL spreadsheet or equivalent.

EASY PLOT statistical graphing package or equivalent.

Although the thermocline in Lake Taupo is usually at about 40 m, the isothermal water column lies below 70 m. To accommodate the gradient across the thermocline, the net VHOD rate calculation only uses oxygen data from below 70 m.

To calculate the mean oxygen concentration in the water column below 70 m, the DO concentration at each 10 m depth increment is multiplied by the volume of the 10 m slice it came from. This assumes rapid horizontal mixing and minimal vertical mixing to extrapolate one DO value across the whole lake. Historical data from multiple sites would suggest that this is a reasonable assumption.

The slice volumes (hypsographic volumes) for Lake Taupo have been calculated for 10 m thick layers centred on the 5 m point of each slice i.e., 75, 85, 95, 105 m etc. The DO measurements are made at 10 m intervals i.e., 70, 80, 90, 100, 110 m etc.

The mass of oxygen in each 10 m slice is the average of the DO concentration at the top and bottom of a slice multiplied by the slice volume. i.e., for the 70 - 80 m slice the calculation is:-

$$\text{mass}_{70-80m} = ((\text{DO}_{70m} + \text{DO}_{80m}) \div 2) \times \text{Volume}_{70-80m}$$

For each profile date:

Compute the mass for each 10 m slice between 70 m and 150 m and sum the results as the total mass of DO in the hypolimnion below 70 m. Sum the slice volumes below 70 m as the total volume of the hypolimnion below 70 m.

The volume weighted mean DO concentration is the total mass value divided by the total volume value.

Use the sequential day number or equivalent to construct a time series of volume weighted mean DO concentrations over the stratified period and use the CURVE FIT regression analysis of EASY PLOT to obtain the $y = ax + b$ straight line fit for these data.

As the DO data are in g m^{-3} , the value of 'a' is in $\text{g m}^{-3} \text{ d}^{-1}$. Multiply 'a' by 1000 to get the net VHOD rate in $\text{mg m}^{-3} \text{ d}^{-1}$. The negative sign indicates a loss rate.

The hypsographic volumes and upper surface areas of the 10 m slices through the whole depth of Lake Taupo are listed at the end of this section.

Lake Taupo Hypsographic Data used in the Net VHOD RATE calculation.

Slice depths (m)	Volume of slice (km^3)	Upper surface area of slice (km^2)
0 - 10	5.849359	600

Statistical evaluation of the VHOD rate

From the 1999-2000 monitoring report (Gibbs 2000b), the VHOD rate is expressed as the calculated net VHOD rate \pm the 95% confidence limit. This gives a meaningful estimate of the range within which the VHOD rate lies and is more appropriate than the standard deviation on the data or a standard error estimate on the regression coefficient.

**Julian Date or sequential day number for each day of the year excluding leap years.
For Leap Years, add 1 to the sequential day number from 1 March to 31 December of that year.**

10. Appendix 3. Temperature and dissolved Oxygen data

Includes accumulated data since 1994.

* represents data missing or invalid.

For completeness, additional data from the Kuratau Basin (site B) and Western Bays (site C) collected for the period between January 2002 and December 2004 are included as separate sheets following the mid-lake data from site A for those years.

Note: unless otherwise stated, the data presented is from the mid-lake site, Site A.

Lake Taupo Temperature, Dissolved Oxygen, and Secchi Depth Database.
Mid-Lake site A for the period starting 4 September 2006

2006-2007

11. Appendix 4. Nutrient data

Includes accumulated 10-m tube data since 1994. Blank cells represent missing data.

For completeness, 10-m tube data collected from the Kuratau Basin (site B) and Western Bays (site C) from January 2002 to December 2004 are included as separate sheets following the mid-lake data from site A for those years.

In the spring/autumn profile data, two different analytical methods are used to measure particulate nitrogen: (1) A wet digestion method involving high temperature refluxing in digestion mixture [persulphate / sulphuric acid / Selenium catalyst] for 3 hours followed by colorimetric determination of the nitrogen as the ammoniacal form, and (2) a CHN combustion method which converts all nitrogen compounds to N₂ gas in a furnace at ~1000°C to be measured in a thermal conductivity detector.

Particulate nitrogen analysed by the wet digestion method may not include some refractory nitrogen components which may be detected by the CHN combustion furnace method. Consequently the PN value from the CHN combustion furnace method should always be greater than or equal to the PN value obtained by the wet digestion method. Occasionally they are reported as less than the wet digestion method value in which case the wet digestion value should be regarded as correct. The cause of this difference is unknown but may be associated with the presence of low molecular weight organic nitrogen compounds lost during the drying step before combustion. The PN values for the time series data are all from wet digestion method analyses and hence are directly comparable with the profile data.

Low level NH₄-N results are likely to be subject to interference from low molecular weight DON and hence may not be biologically available for phytoplankton growth.

From February 2002, DRP, NO₃-N, and NH₄-N were measured on a Lachat Flow Injection Analysis (FIA) system but using essentially the same chemistry as previously used on the Technical Auto-Analyzer system. The reported detection limits for these nutrients remains the same at 0.5 mg m⁻³ for DRP and NO₃-N, and 1 mg m⁻³ for NH₄-N, however, the greater precision of the FIA system provides confidence in reporting results to a lower level as an indication of likely absolute values near zero. Such values are provided as an indication only and the true value should be expressed as less than the detection limit. TN and TP values are the sum of all other N and P components, excluding Urea-N which is part of the DON component. All analytical values ‘on-the-day’ are used wherever possible or <DL = DL/2 for summation in TN and TP.

The DON value for 5/08/2000 was corrected from 12 to 43.5 in March 2006. This was a transcription error from the original analytical result sheet.

Lake Taupo cumulative database of 10m tube sample data from October 1994 to September 2002.
Samples collected from central lake site.

 NH₄, NO₃, DON, Urea all as N

* = PN by wet digestion method, ** = PN by combustion furnace method.

 Detection limits: DRP 0.5; NO₃-N 0.5; NH₄-N 1.0 mg m⁻³

New Analytical instrument (Flow Injection Analysis) from January 2002, gives greatly improved resolution at low levels.

 FIA instrument results are given as a better indication of likely absolute low levels of DRP, NO₃-N, and NH₄-N below nominal detection limit.

 NH₄, NO₃, DON, Urea all as N

* = PN by wet digestion method, ** = PN by combustion furnace method.

 Detection limits: DRP 0.5; NO₃-N 0.5; NH₄-N 1.0 mg m⁻³

New Analytical instrument (Flow Injection Analysis) from January 2002, gives greatly improved resolution at low levels.

 FIA instrument results are given as a better indication of likely absolute low levels of DRP, NO₃-N, and NH₄-N below nominal detection limit.

NH₄, NO₃, DON, Urea all as N

* = PN by wet digestion method, ** = PN by combustion furnace method.

Detection limits: DRP 0.5; NO₃-N 0.5; NH₄-N 1.0 mg m⁻³

New Analytical instrument (Flow Injection Analysis) from January 2002, gives greatly improved resolution at low levels.

FIA instrument results are given as a better indication of likely absolute low levels of DRP, NO₃-N, and NH₄-N below nominal detection limit.

* = analysed by wet digestion method, ** = analysed by CHN combustion furnace method.

12. Appendix 5. Phytoplankton data

In this report there is a transition from just reporting “Dominance” (rank 1 = dominant to rank 10 = rare), which is calculated from algal biovolume, to reporting cell counts plus biovolume. Both systems are presented in this report. For continuance of the Dominance format, rank the species composition by biovolume.

Note: reporting counts as cells per ml rounded to a whole number may result in cell counts of “0” despite a large biovolume where the algal species is large or colonial e.g., *Botryococcus braunii*

Lake Taupo phytoplankton dominance plus enumeration (10-m tube) 2006-07

Dominance by biovolume (rank 1 = dominant,...rank 10 = rare), plus cell counts and biovolume from May 2007

13. Appendix 6. Historical data

Historical data held by NIWA has frequently been referred to and included in some analysis or comparison of the data from the long-term monitoring programme. To ensure that this data is always readily available, copies of the relevant historical data are included in this report. These data are the spring and autumn profiles of NO₃-N and DRP from 1974 to 1990 extracted from archived data books. The nitrate data for 27 September 1979 was taken from Vincent (1983). Subsequent data can be found in the appendices above.

Note that the profiles given are aligned with the spring data above the corresponding autumn data, by date. Note also that the early profiles were to a depth of 110 m rather than 150 m. Also, as there was no March or April data collected in 1976, for completeness, the last valid profile in that series (12 January 1976) has been included.

The elapsed time given is the number of days between the spring profile in about October and the autumn profile in March/April of the following year. The average elapsed time between the two samplings across all data from 1974 to 2006 is 165 days.

The historical data also include an un-paired profile from July 1987. As there were no data for April 1987 and the lake was still stratified in July, when the next period of monitoring began, the July 1987 may be used as an indication of the total mass of nutrient accumulation in that year. Because these data are for an un-paired profile in July and not April, if the data are converted to rate estimates the assumption must be made that there was no spring carryover and the elapsed time is longer being estimated as the average elapsed time plus three months.

Because the 1976 and 1987 data are for periods other than spring (October/November) to autumn (March/April), these data points have been excluded from any regression analysis of time-series data although the data points have been plotted as an indication of levels/rates for those years.
